When more than a thiazide is needed...

ALDOMET® TABLETS 500 mg, 250 mg, and 125 mg

(METHYLDOPA | MSD

an agent well matched to the profile

With increasing age...
incidence of certain concurrent disorders increases

ALDOMET may be used in a wide range of older hypertensives, including those with:

- **ventricular hypertrophy/cardiac failure***
- **peripheral vascular disease**
- **diabetes mellitus**
- **hyperuricemia/gouty arthritis**

judicious exercise may be desirable

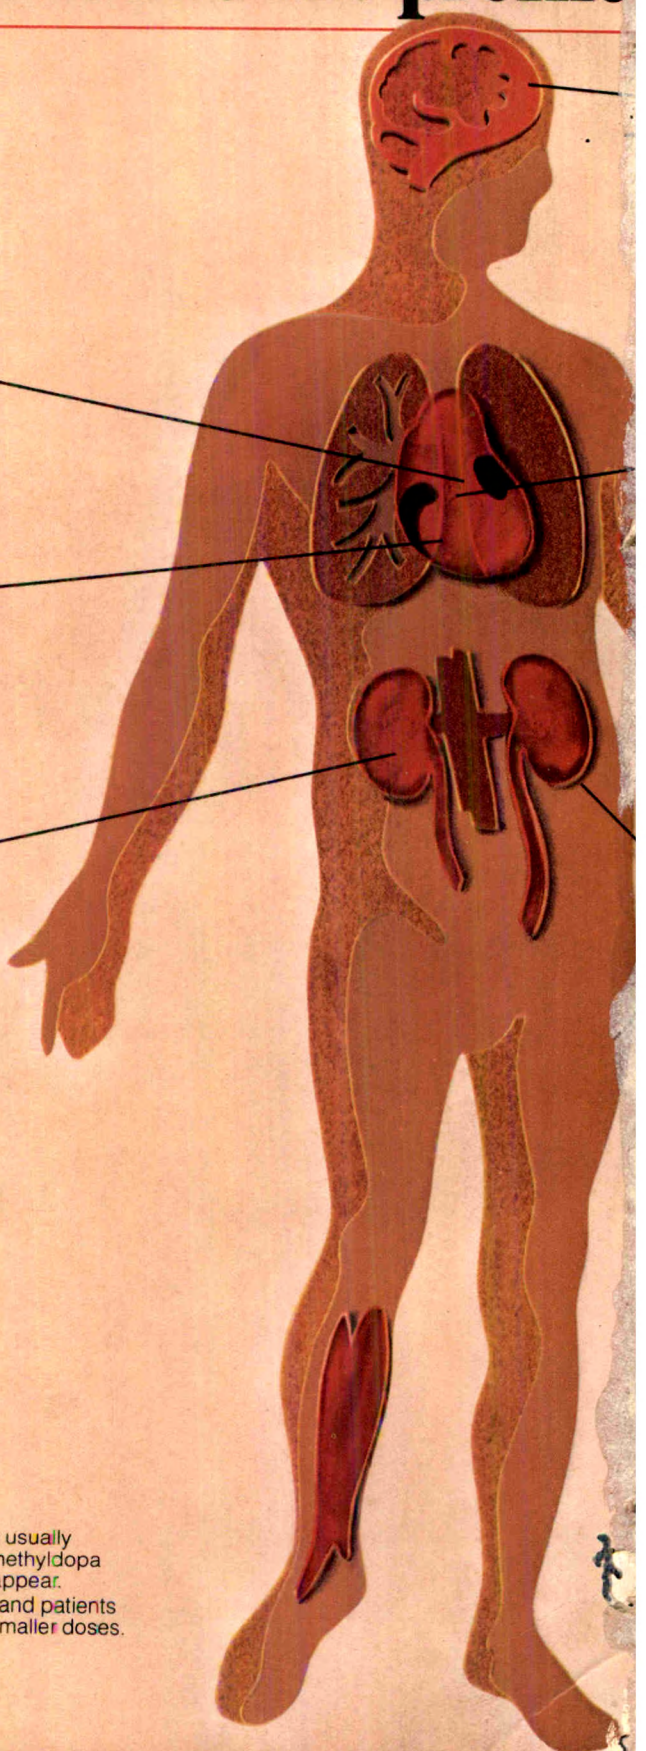
ALDOMET usually does not interfere with the cardiovascular response to exercise.

renal function often diminished

ALDOMET usually does not reduce glomerular filtration rate, renal blood flow, or filtration fraction.†

compliance often a problem

ALDOMET provides b.i.d. dosage convenience for many patients.



*Edema (and weight gain) may occur and may usually be relieved by use of a diuretic. Discontinue methyldopa if edema progresses or signs of heart failure appear.

†Methyldopa is largely excreted by the kidney, and patients with impaired renal function may respond to smaller doses.

Copyright ©1981 by Merck & Co., Inc. All rights reserved.

# of a wide range of older hypertensives

ability to autoregulate cerebral blood flow with postural changes often decreased

With ALDOMET® (Methyldopa, MSD), symptomatic postural hypotension is infrequent. Syncope in older patients may be avoided by lower doses.

cardiac output and heart rate usually normal

ALDOMET has no direct effect on cardiac function, and cardiac output usually is maintained.

total peripheral resistance usually high

ALDOMET lowers blood pressure, apparently by lowering total peripheral resistance.

ongoing therapy usually required

ALDOMET has demonstrated a high degree of efficacy in long-term therapy.

plasma renin activity usually low but may be normal or high

With ALDOMET, normal or elevated plasma renin activity may decrease.

ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, or if previous methyldopa therapy has been associated with liver disorders.

It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

Syncope in older patients may be related to an increased sensitivity and advanced arteriosclerotic vascular disease. This may be avoided by lower doses.

MSD
MERCK SHARP & DOHME

For a Brief Summary of Prescribing Information, please see following page.

ALDOMET® (Methyldopa/MSD)

Tablets, containing 125, 250, or 500 mg methyldopa; Oral Suspension, containing 250 mg methyldopa per 5 ml and alcohol 1%.

Contraindications: Active hepatic disease, such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions. With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood. At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients. Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression. *Cardiovascular:* Bradycardia, prolonged carotid sinus hypersensitivity, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.) *Gastrointestinal:* Nausea, vomiting, distention, constipation, flatus, diarrhea, colitis, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis. *Hepatic:* Abnormal liver function tests, jaundice, liver disorders. *Hematologic:* Positive Coombs test, hemolytic anemia. Bone marrow depression, leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor. *Allergic:* Drug-related fever, lupus-like syndrome, myocarditis. *Dermatologic:* Rash as in eczema or lichenoid eruption; toxic epidermal necrolysis. *Other:* Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, hyperprolactinemia, amenorrhea, impotence, decreased libido, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

For more detailed information, consult your MSD Representative or see Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., INC., West Point, PA 19486

The Editorial Board

Shortly after becoming Editor of the *AJC*, I began reflecting on physicians who I would ask to serve as editorial board members. I realized immediately that a *large board* would be essential if the board members, rather than outside consultants, were to be the primary reviewers of manuscripts submitted to the *Journal*. Each major and minor subspecialty of cardiology needed to be represented by several respected investigators. I was particularly anxious to increase the representation of cardiovascular surgeons because their role is a vital one in the present-day management of patients with cardiovascular disease, and because in the past they have been underrepresented on the boards of cardiology journals.

I also realized immediately that many individuals I would want on the new editorial board would already be members of one or more other editorial boards. In the past I have had the privilege of serving simultaneously on the editorial boards of 6 different medical journals, and as a reviewer I have paid little attention to the name of the journal for which I was reviewing a manuscript. An editorial board member's expertise is not the monopoly of a single medical journal. The board member's charge is to evaluate promptly the scientific quality of a manuscript and the means to improve that manuscript. Board-member reviewers, as do nonboard reviewers, serve the entire medical community by providing expert opinions to any editor who asks them to do so. They do not and should not take a loyalty oath to a specific journal—their loyalty is to the writer and the reader. Placing a reviewer on an editorial board gives him public recognition as a superb manuscript reviewer and is the means by which the editor says "thanks" for his help. If one editor rewards a reviewer by placing him on his editorial board, that action should not prevent another editor from rewarding the same reviewer similarly. Indeed, membership on more than one editorial board is further acknowledgment of a reviewer's sought-after expertise. Just as the medical writer (investigator) is free to submit his manuscript to any journal he chooses, the expert reviewer is free to provide his expertise to any journal so requesting. If an *AJC* board member is a member of another editorial board, that is the business of the editorial board member and the other journal, and of no concern to the present Editor of the *AJC*.

After establishing the principle that a large editorial board would be necessary, I prepared lists of adult and pediatric cardiologists, cardiac surgeons, and related specialists such as radiologists, pathologists, and pharmacologists, and in July 1982 I began dialing the telephone. I initially contacted 110 potential editorial board members, 103 of whom accepted the invitation. I am grateful and indeed the entire cardiovascular community must be grateful to these expert manuscript reviewers who devote their time freely to improving the quality of articles published in our medical journals.

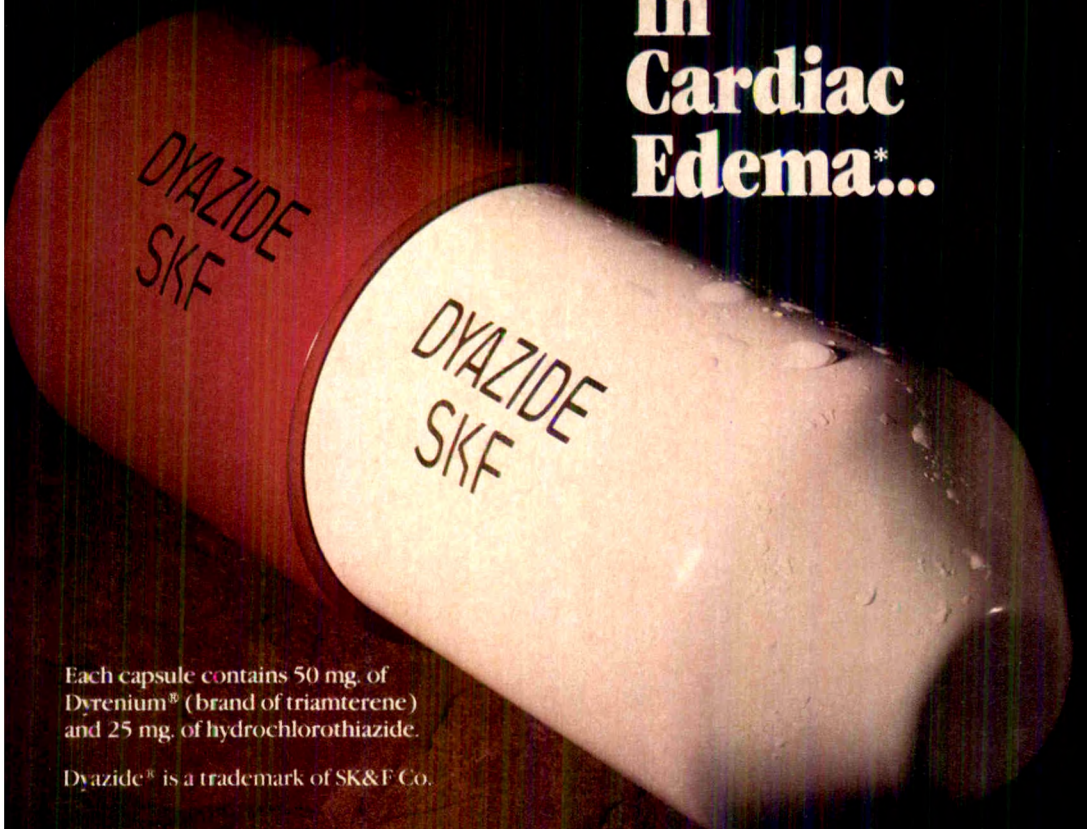
William C. Roberts, MD
Editor-in-Chief

In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

When You Need to Conserve K^+

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis and of impotence have been reported with the use of Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak® unit-of-use bottles of 100.

ARRHYTHMIAS

Cardiovascular well-being often begins with Inderal®
(PROPRANOLOL HCl)

No agent offers a better risk/benefit profile in arrhythmias than INDERAL (propranolol HCl). INDERAL works to reduce heart rate and contractility, lengthen A-V conduction time, and suppress automaticity[1]—helping to restore the heart rate to normal in many patients with a wide variety of arrhythmias.

Consider INDERAL for arrhythmias early—to restore cardiovascular well-being as soon as possible.

Reference: 1. AMA Department of Drugs: AMA Drug Evaluations, ed. 4. Littleton, Mass., Publishing Sciences Group, Inc., 1980, p. 520.

Please see Brief Summary of Prescribing Information on the following page.

INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.

INDERAL®
(PROPRANOLOL HCl)

To restore cardiovascular well-being.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure, intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

500 mg

Our family is growing

Announcing a new dosage strength

750 mg

SUSTAINED RELEASE

Procan® SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

Proved bioequivalent at steady state to the Procan SR 500-mg tablet* by proportional plasma levels.

For patients with atrial fibrillation and paroxysmal atrial tachycardia. While individual dosage should be titrated, for many adults with ventricular tachycardia, the suggested maintenance dose is 0.75 gram q6h. With our new 750-mg scored tablet, the physician can now administer one tablet q6h to maintain procainamide blood levels all day and all night.

*Based on a randomized, two-way crossover trial following multiple-dose administration to 12 subjects (data on file, Medical Affairs Dept, Parke-Davis).

Procan SR... The original sustained-release oral procainamide. Now it provides the dosage versatility you need!

PARKE-DAVIS

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests —Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia —Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia —Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet, P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet, P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet, P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

DIASONICS/OEC

A REVOLUTION IN CARDIAC

A price/performance breakthrough in a

IT'S WHERE CARDIAC IMAGING IS GOING...

DIGITAL ANGIOGRAPHY

completely integrated system—AngioVue

The First Stand-Alone System for Intravenous Ventriculography

Only DIASONICS/OEC could do it! By integrating the OEC 9-inc C-Arm with DIASONICS DA-100™ Digital Angiographic Imaging Sys an exciting new cardiac imaging system has been developed. Angio The first stand-alone system for intravenous digital ventriculograph With AngioVue you may now perform digital subtraction studies in or out of the cath lab. A powerful, efficient approach to the expandi new field of digital angiography.

High Resolution Digital Imaging with Maximum C-Arm Mobility.

The AngioVue's unique system architecture has been designed specifically for cardiac applications. It provides outpatient ventricu raphy capability with better image resolution than nuclear cardiol Because it's a stand-alone, mobile system, AngioVue is ideal for beds imaging in the CCU/ICU. And its high-contrast resolution is the key to its use in PTCA, streptokinase infusion and vascular imaging.

With the AngioVue system, images are presented in real time for faster, more precise diagnoses. It gives you C-Arm positioning capal and a wider field of view with a 9-inch image intensifier. And the AngioVue system can also be interfaced to a second X-ray system (cath lab, X-ray room).

AngioVue: Leading the Way in Digital Angiography.

- ☐ Totally digital image storage/processing for improved resolutio
- ☐ Maximum C-Arm versatility for ease of patient positioning
- ☐ Complete real-time imaging and quantitative analysis includir
  - Volumetric Determinations
  - Ejection Fraction
  - Regional Wall Motion Analysis
  - Functional Imaging
- ☐ Dual room interface with any cath lab equipment
- ☐ Standard fluoro capability for pacemakers and catheter placem

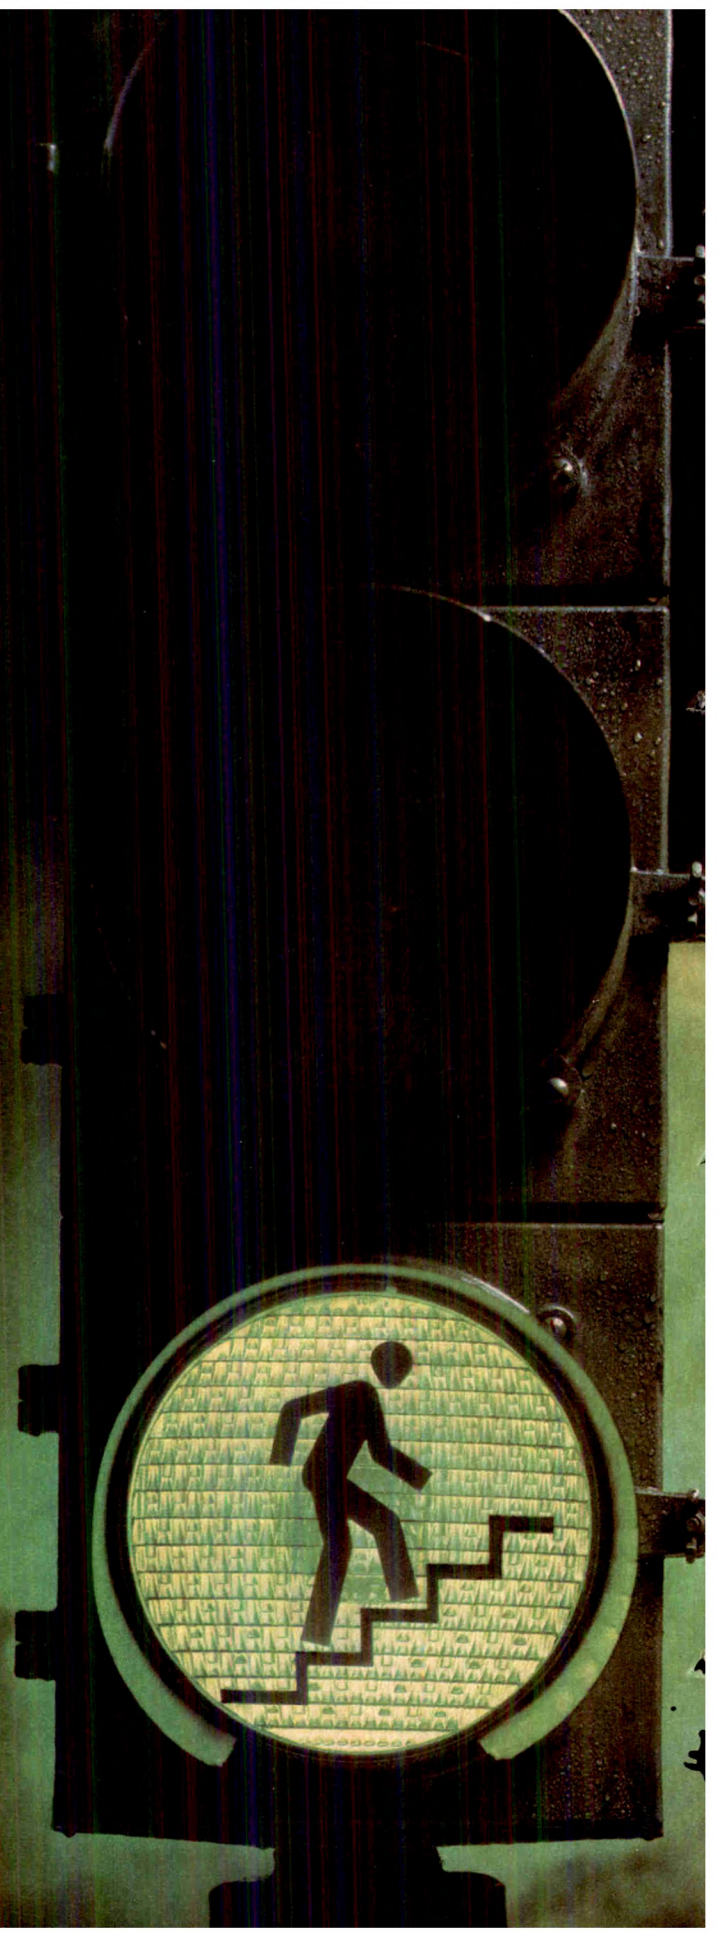
SEARLE

CHANGING ANGINA THERAPY

Calan™
(verapamil HCl)
TABLETS
80 mg and 120 mg

The Prototype Calcium Antagonist

Please see the following page for a brief summary of the complete prescribing information.



Calan TABLETS 80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction < 30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR < 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

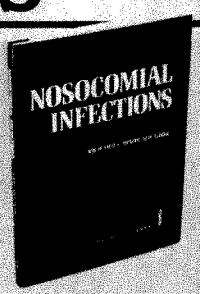
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

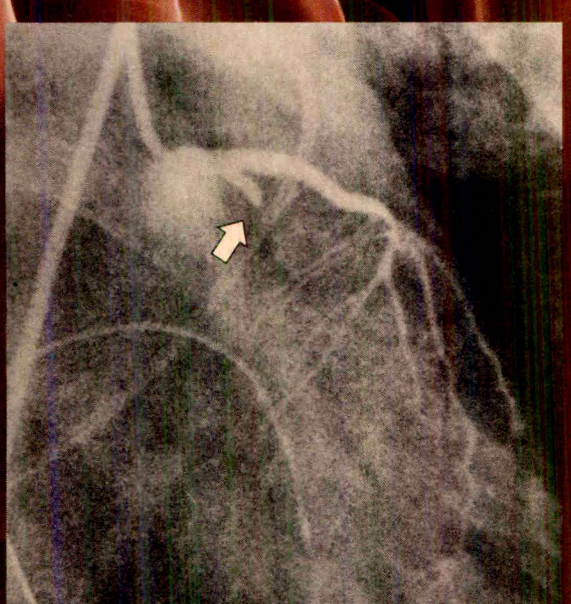
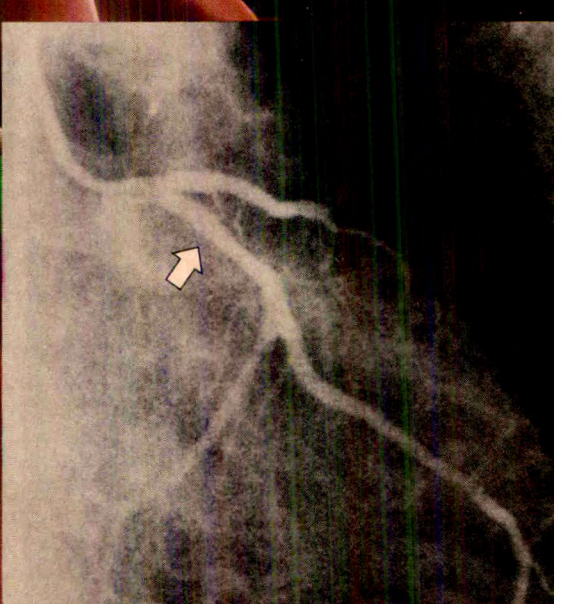
in evolving transmural myocardial infarction

New therapy quickly dissolves acute coronary artery thrombi



Pre-streptokinase
A 38-year-old woman in cardiogenic shock with acute lateral wall myocardial infarction caused by complete left circumflex occlusion (arrow).



Post-streptokinase
The left circumflex is now widely patent beyond previous site of obstruction (arrow).

Please see full prescribing information, a summary of which appears on the last page of this ad.

STREPTASE®
(streptokinase)

now indicated for acute coronary artery thrombosis.

Streptase® is infused directly into the involved artery during cardiac catheterization.

Efficacy demonstrated in multicenter studies

Coronary artery reperfusion was accomplished in 174 of 221 patients (79%) during evolving transmural myocardial infarction.

Randomized, controlled studies are in progress to determine the effects of reperfusion on salvage of myocardial tissue and reduction of mortality.

Side effects: few and readily controlled

There were no reports of allergic reaction or fever. Seven cases of bleeding at the puncture site and one case of moderate peritoneal bleeding were controlled without terminating therapy. Severe bleeding was reported in only one patient. This patient had a gastric ulcer six months prior to treatment.

Prompt initiation of treatment critical

The greatest benefit is achieved when therapy is initiated within six hours after the onset of symptoms.

Thrombolytic activity and safety record well documented

Streptase® has been effectively used worldwide for nearly a decade. Its record of clinical success is well matched by its record of safety, and both have been extensively reported in the medical literature.

STREPTASE®
(streptokinase)

A major advance in M.I. therapy

Please see full prescribing information, a summary of which appears on the following page.

STREPTASE® (streptokinase)
Brief Summary
CONSULT PACKAGE INSERT FOR FULL PRESCRIBING INFORMATION.

INDICATIONS AND USAGE

CORONARY ARTERY THROMBOSIS

Streptase® (streptokinase) has been reported to lyse acute thrombi obstructing coronary arteries, associated with evolving transmural myocardial infarction. Diagnosis of acute myocardial infarction has been confirmed, and the site of coronary thrombosis identified by selective coronary angiography. Other studies have demonstrated that (a) a thrombus is present in approximately 90% of patients evaluated within four hours of onset of symptoms; (b) when compared to concurrent or historical controls, the majority of patients who received intracoronary streptokinase within 6 hours of onset of symptoms showed a more immediate recanalization (within a few minutes vs hours/days) of the involved vessel.

IT HAS NOT BEEN ESTABLISHED THAT INTRACORONARY ADMINISTRATION OF STREPTOKINASE DURING EVOLVING TRANSMURAL MYOCARDIAL INFARCTION RESULTS IN SALVAGE OF MYOCARDIAL TISSUE, NOR THAT IT REDUCES MORTALITY. CONTROLLED STUDIES ADDRESSING THESE PARAMETERS ARE IN PROGRESS AND UNTIL COMPLETED, THOSE PATIENTS WHO MIGHT BENEFIT FROM THIS THERAPY CANNOT BE DEFINED.

CONTRAINDICATIONS

Because thrombolytic therapy increases the risk of bleeding, Streptase® (streptokinase) is contraindicated in the following situations:

- active internal bleeding
- recent (within 2 months) cerebrovascular accident, intracranial or intraspinal surgery (see WARNINGS)
- intracranial neoplasm

WARNINGS

Bleeding

The aim of Streptase® (streptokinase) therapy is the production of sufficient amounts of plasmin for the lysis of intravascular deposits of fibrin; however, fibrin deposits which provide hemostasis, for example, at sites of needle punctures, are also lysed and bleeding from such sites may occur.

Intramuscular injections and nonessential handling of the patient must be avoided during treatment with Streptase® (streptokinase). Venipunctures should be performed carefully and as infrequently as possible.

Should an arterial puncture be necessary during intravenous therapy, upper extremity vessels are preferable. Pressure should be applied for at least 30 minutes, a pressure dressing applied and the puncture site checked frequently for evidence of bleeding.

When internal bleeding occurs, it may be more difficult to manage than that which occurs with conventional anticoagulant therapy.

In the following conditions the risks of therapy may be increased and should be weighed against the anticipated benefits.

- Recent (within 10 days) major surgery, obstetrical delivery, organ biopsy, previous puncture of noncompressible vessels
- Recent serious gastrointestinal bleeding (within 10 days)
- Recent trauma including cardiopulmonary resuscitation
- Severe, uncontrolled arterial hypertension
- High likelihood of left heart thrombus, e.g., mitral stenosis with atrial fibrillation
- Subacute bacterial endocarditis
- Hemostatic defects including those secondary to severe hepatic or renal disease
- Pregnancy
- Cerebrovascular disease
- Diabetic hemorrhagic retinopathy
- Prior severe allergic reaction to streptokinase
- Septic thrombophlebitis or occluded AV cannula at seriously infected site
- Any other condition in which bleeding constitutes a significant hazard or would be particularly difficult to manage because of its location.

Should serious spontaneous bleeding (not controllable by local pressure) occur, the infusion of Streptase® (streptokinase) should be terminated immediately and treatment instituted as described under ADVERSE REACTIONS.

Use of Anticoagulants

Concurrent use of anticoagulants with intravenous administration of Streptase® (streptokinase) is not recommended. However, concurrent use of heparin may be required during intracoronary administration of Streptase® (streptokinase). Clinical studies with concurrent use of heparin and lower Streptase® (streptokinase) dosages employed during intracoronary administration have demonstrated no tendency toward increased bleeding that would not be attributable to the procedure or Streptase® (streptokinase) alone. Nevertheless, careful monitoring for excessive bleeding is advised.

Arrhythmias

Rapid lysis of coronary thrombi has been reported occasionally to cause reperfusion atrial or ventricular dysrhythmias requiring immediate treatment. During studies, careful monitoring for arrhythmia was maintained during and immediately following intracoronary administration of Streptase® (streptokinase).

PRECAUTIONS

Use in Pregnancy and Children

Safety and effectiveness of Streptase® (streptokinase) therapy in children and during pregnancy have not been established. Therefore, treatment of such patients is not recommended.

Drug Interactions

The interaction of Streptase® (streptokinase) with other drugs has not been studied. Drugs that alter platelet function should not be used during therapy. Common examples are: aspirin, indomethacin, and phenylbutazone.

Patient Monitoring

Before commencing thrombolytic therapy, it is desirable to obtain a thrombin time (TT), activated partial thromboplastin time (APTT), prothrombin time (PT), hematocrit and platelet count to obtain hemostatic status of the patient.

Intracoronary Artery Infusion

During studies, laboratory monitoring of hemostatic parameters during intracoronary artery infusion showed minimal changes, if any. Heparin was continued during therapy or instituted following therapy and monitored accordingly.

ADVERSE REACTIONS

The following adverse reactions have been frequently associated with intravenous therapy but may also occur with intracoronary artery infusion:

Bleeding

Minor bleeding occurs often with thrombolytic therapy mainly at invaded or disturbed sites. When lytic therapy is continued while local measures are used to control minor bleeding, do not reduce the dose as this will increase lytic activity since more plasminogen will be available for conversion to plasmin. Severe internal bleeding involving gastrointestinal, genitourinary, retroperitoneal or intracerebral sites, may occur. Several fatalities due to cerebral and other serious internal hemorrhage have occurred during intravenous thrombolytic therapy.

Should uncontrollable bleeding occur, Streptase® (streptokinase) infusion should be discontinued and, if necessary, blood loss and reversal of the bleeding tendency can be effectively managed with whole blood (fresh blood preferable), packed red blood cells and cryoprecipitate or fresh frozen plasma. Although the use of aminocaproic acid (ACA, AMICAR®) in humans as an antidote for streptokinase has not been documented, it may be considered in an emergency situation.

Allergic Reactions

Reactions attributed to possible anaphylaxis have been observed rarely in patients treated with Streptase® (streptokinase) intravenously. These ranged in severity from minor breathing difficulty to bronchospasm, periorbital swelling or angioneurotic edema. Other milder allergic effects such as urticaria, itching, flushing, nausea, headache and musculoskeletal pain have also been observed.

Mild or moderate reactions may be managed with concomitant antihistamine and/or corticosteroid therapy. Severe allergic reactions require immediate discontinuation of Streptase® (streptokinase), with adrenergics, antihistamines, or corticosteroids administered intravenously as required.

Fever

Although Streptase® (streptokinase) is nonpyrogenic in standard animal tests, approximately one-third of patients treated with Streptase® (streptokinase) intravenously have shown increases in body temperature of ≥ 1.5°F. Symptomatic treatment is usually sufficient to alleviate discomfort. The use of acetaminophen rather than aspirin is recommended.

DOSAGE AND ADMINISTRATION

Lysis of Coronary Artery Thrombi

During clinical studies, Streptase® (streptokinase) was administered selectively into the thrombosed coronary artery via coronary catheter placed by the Judkins or Sones Technique. When administered within 6 hours of onset of symptoms of acute transmural myocardial infarction, at a bolus dose averaging 20,000 IU and a maintenance dose averaging 2,000 IU/min for 60 minutes, greater than 75% of occlusions were opened in less than 1 hour.

How Supplied

Streptase® (streptokinase) is supplied as a lyophilized white powder in 6.5 mL vials (in packages of 10) with color-coded labels corresponding to the amount of purified Streptase® (streptokinase) in each vial as follows:

green — 250,000 IU blue — 750,000 IU

Store unopened vials at controlled room temperature (15-30°C).

CLINICAL STUDIES

663 Medical Versus Surgical Treatment of Unstable Angina

HERBERT N. HULTGREN, UDIPI R. SHETTIGAR, and D. CRAIG MILLER

A prospective, nonrandomized data bank study of the effect of medical versus surgical management of unstable angina included all patients with unstable angina seen at 1 hospital over an 8 year period. All patients had an initial 5 day period of medical treatment. Surgery was performed in 104 patients (operative mortality 2%) and medical treatment was continued in 124 patients. After a mean follow-up period of 52 months, 7 year survival (Mantel-Haenszel) was 65% for the medical group and 85% for the surgical group when analyzed by initial treatment ($p = 0.012$). Analysis of survival by the crossover method where crossover medical patients are followed only to the date of surgery showed a similar improvement in survival in surgical patients ($p = 0.008$). Nonsurvivors had a higher incidence of the following entry features than survivors: (1) age greater than 60 years, (2) diastolic hypertension, (3) ST-T changes at rest, (4) 3 vessel disease, and (5) elevated left ventricular diastolic pressure. No patient who died had single-vessel disease. Surgical treatment improves survival in patients with unstable angina, especially those with adverse prognostic features.

671 Characteristics of Survivors of Exertion- and Nonexertion-Related Cardiac Arrest: Value of Subsequent Exercise Testing

W. DOUGLAS WEAVER, LEONARD B. COBB, and ALFRED P. HALLSTROM

Ninety ambulatory patients who had previously been resuscitated from out-of-hospital ventricular fibrillation had subsequent exercise testing and further follow-up to determine possible predictors of further episodes of cardiac arrest. About one third had had the initial episode of cardiac arrest during exertion-related activities, and 30% of the total group of 90 patients died during the 2 year follow-up. There was no greater evidence of "ischemia" before cardiac arrest in those with exertion-related cardiac arrest than in the nonexertion group. Exercise testing provoked a similar incidence of S-T depression; complex ectopy was evoked more often in the nonexertion-related group. Exercise test-evoked angina or failure to augment systolic blood pressure were strongly associated with subsequent fatal events during the follow-up period. There were no clinical or exercise characteristics unique to patients who collapsed during exertion. Routine exercise testing was of limited value in predicting subsequent fatal events in patients previously resuscitated from ventricular fibrillation.

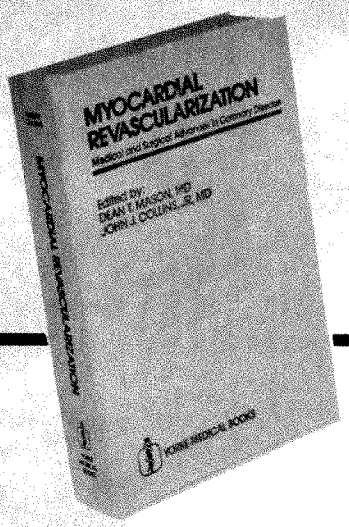
LIBRARY



MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-in-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

Sophisticated New Approaches for Today's Informed Cardiologist...

BASIC ELECTROCARDIOGRAPHY AND VECTORCARDIOGRAPHY
by Julian Ruffin Beckwith
(with a contribution from Lockhart B. McGuire)

This well-organized softcover volume is the ideal student text and an excellent reference for house staff and physicians. The author systematically explains how to construct the EKG and vectorcardiogram, describes the abnormal EKG in common disease states, and demonstrates the usefulness of vector analysis in interpreting EKG abnormalities. The text includes a discussion of the principles and clinical applications of intracavitary recordings of the activation of specialized conduction tissues ("His bundle electrogram.") Dr. McGuire's chapter on cardiac rhythms offers practical guidelines for recognizing abnormal rhythms and identifying rhythms in uncertain situations. Numerous illustrations accompany the text, and an Appendix contains illustrative EKG's and corresponding VCG loops.

CARDIOVASCULAR DRUGS AND THE MANAGEMENT OF HEART DISEASE
Gordon A. Ewy and Rubin Bressler, editors

Every cardiologist, cardiovascular surgeon, and internist will welcome this practical, authoritative guide to the use of cardiovascular drugs and the management of cardiac disorders. In a clear, convenient format, it offers expert information on the indications, dosage, clinical pharmacology, side effects, and contraindications of all the drugs now available. It also provides realistic guidelines for the diagnosis and management of cardiovascular problems based on the most up-to-date scientific information and the authors' extensive clinical experience.

LEUKOTRIENES AND OTHER LIPOXYGENASE PRODUCTS
(Advances in Prostaglandin, Thromboxane, and Leukotriene Research, Vol. 9)
Bengt Samuelsson and Rodolfo Paoletti, editors

The recent discovery of leukotrienes has created a considerable stir within the medical-scientific community. This volume is the first comprehensive survey of our knowledge of these important compounds. It provides complete coverage of the biosynthesis and metabolism of leukotrienes and lipoxygenase products, the pharmacological modulation of leukotriene formation, and the biological effects of leukotrienes. Major findings presented include: the leukotrienes' role in the formation of SRS-A, the involvement of SRS-A in hypersensitivity reactions, the leukotrienes' role in inflammation, the interactions between leukotrienes and cyclo-oxygenase products, and the biological effects of leukotrienes and SRS-A antagonists.

CARDIOVASCULAR PHARMACOLOGY OF THE PROSTAGLANDINS
Arnold V. Herman, Paul M. Vanhoutte, Henri Denolin and Albert Goossens, editors

A detailed examination of the role of prostaglandins in the regulation of the cardiovascular system and therapy of cardiovascular diseases. Their synthesis, metabolism, and modulation by endogenous substances and drugs, and their effects on the circulatory system, are treated at length. Also included are chapters on atherosclerosis and prostacyclin, dietary manipulation of prostaglandin synthesis, and the role of drugs in the modulation of platelet function in specific conditions like ischemic heart disease. This volume is an indispensable addition to the reference library of cardiologists, cardiovascular pharmacologists, and physiologists.

For **every** professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

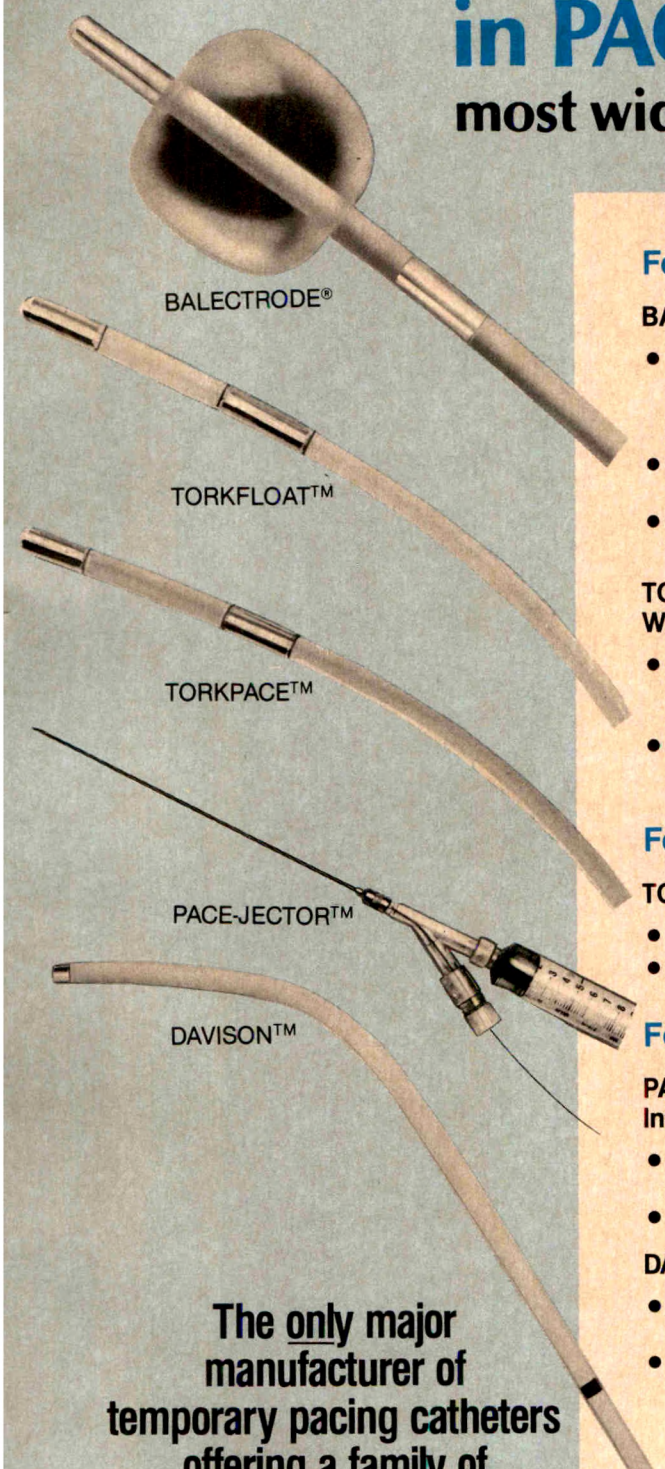
ELECATH®...Leading the way in PACING CATHETERS

most widely used...widest selection



For Placement *without* Fluoroscopy

BALECTRODE® Balloon Flow-Directed Pacing Kit

- The *only* major manufacturer of Balloon Flow-Directed pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response, and to prevent the migration effect seen in stainless steel electrodes.
- Two French sizes are available: 3 French (KBE1) and 5 French (KBE2) for various patient physiological requirements.
- Complete sterile kit, consisting of an introducer, shielded EKG adapter, and vented syringe for exact, accurate balloon inflation.

TORKFLOAT™ Semi-Floating Pacing Kit With 1:1 Torque Response

- The *only* major manufacturer of semi-floating pacing products to offer non-corroding *platinum* electrodes to assure optimal physiological response.
- Complete kit includes pacing catheter with centimeter markings, introducer and sterile shielded EKG adapter for artifact-free EKG tracing, for confirmation of placement.

For Placement *with* Fluoroscopy

TORKPACE™ Standard Pervenous Pacing Probes

- *Platinum* electrodes to assure optimal physiological response.
- Hybrid inner core design provides a semi-flexible catheter tip for better flexibility for permanence of position and safety.

For Emergency Pacing

PACE-JECTOR™—The Unique Dual Purpose Pacing And Intracardiac Medication System (11-KPJ1)

- Direct electrical stimulation and/or pharmacological manipulation of the unresponsive myocardium is immediately available.
- The pacing stylet is *pre-loaded* for simple intraventricular placement.

DAVISON™—Emergency Transvenous Pacing Lead (11-KTFD)

- Capture achieved as soon as the proximal electrode emerges from the introducer sheath.
- *Platinum* electrodes located 19cm apart assure conduction system stimulation regardless of catheter tip position in the ventricle.

The only major manufacturer of temporary pacing catheters offering a family of non-corrosive platinum electrodes.

ELECTRO-CATHETER CORPORATION

CONTENTS

677 Quantitative Comparison of Extent of Coronary Narrowing and Size of Healed Myocardial Infarct in 33 Necropsy Patients With Clinically Recognized and in 28 Necropsy Patients With Clinically Unrecognized ("Silent") Previous Acute Myocardial Infarction

HENRY SCOTT CABIN and WILLIAM C. ROBERTS

Clinical and necropsy observations are described in 61 patients with a healed transmural myocardial infarction, 33 with and 28 without a clinical history of acute myocardial infarction. Compared with the patients who had clinically recognized acute myocardial infarction, the patients with clinically unrecognized ("silent") infarction had a significantly ($p < 0.05$) higher incidence of diabetes mellitus (43 versus 15%), death from noncardiac causes (39 versus 9%), posterior (inferior) wall infarcts (82 versus 55%), and smaller infarcts (mean size 7 versus 17% of left ventricular wall).

682 Anatomic and Prognostic Implications of an Early Positive Treadmill Test

RICKY M. SCHNEIDER, JOHN F. SEAWORTH, MARY L. DOHRMANN, ROBERT M. LESTER, HARRY R. PHILLIPS, THOMAS M. BASHORE, and JOHN T. BAKER

Eighty men with clinical coronary artery disease were catheterized regardless of symptoms and previous therapy because they had a positive treadmill test in stage I or II of the Bruce protocol. Left main coronary artery stenosis of 50% or greater of the vessel diameter was found in 28% of these patients. Fifty-four patients from this group who did not have left main stenosis of 50% or greater were treated medically. In this subgroup, 85% had 2 or 3 major coronary vessels with 75% or greater stenosis. These patients had a 36 month survival rate of 89.2%. Thus, an early positive treadmill test identifies patients with an increased likelihood of having left main stenosis, even if they have minimal symptoms. After left main stenosis has been excluded by cardiac catheterization, these patients may be treated medically with a low mortality.

689 Effect of Nifedipine on Exercise-Induced Left Ventricular Dysfunction and Myocardial Hypoperfusion in Stable Angina

NADIM M. ZACCA, MARIO VERANI, ROBERT A. CHAHINE, and RICHARD R. MILLER

The present study was designed to assess the effects of nifedipine on left ventricular function at rest and during exercise in 15 patients with coronary artery disease and stable angina pectoris. Myocardial perfusion scintigraphy was also performed in 11 of the 15 patients in an attempt to elucidate the mechanism underlying such effects in these patients. Nifedipine was shown to improve left ventricular performance in general in those patients. It significantly improved the rest as well as the peak exercise ejection fraction. Importantly, it caused no significant deterioration in ejection fraction or in regional wall motion in any patient. In fact, it decreased the deterioration in regional wall motion from rest to peak exercise. In certain patients, nifedipine appeared to improve exercise-induced myocardial perfusion defects.

696 Randomized Double-Blind Comparison of Verapamil and Nifedipine in Chronic Stable Angina

V. BALA SUBRAMANIAN, MICHAEL J. BOWLES, NARDEV SINGH KHURMI, ANTHONY B. DAVIES, and EDWARD B. RAFTERY

The antianginal efficacy of 2 calcium antagonists, verapamil (360 mg/day) and nifedipine (60 mg/day), were compared in a double-blind randomized crossover trial in 32 patients with chronic stable angina. Maximal treadmill exercise testing with on-line computer analysis of the electrocardiogram, 24 hour Holter monitoring using a frequency-modulated cassette tape recorder, and systolic time intervals were the criteria used for evaluating efficacy and safety. Twenty-eight patients completed the trial. Both drugs improved exercise tolerance and other objective variables of ischemia, and the results achieved with verapamil were significantly better than those with nifedipine. Palpitations and angina were reported by 4 patients after taking nifedipine; Holter monitoring revealed episodes of tachycardia associated with S-T depression. Verapamil appears more efficacious and better tolerated in the therapeutic dose range in patients with chronic stable angina.

704 Hemodynamic and Electrophysiologic Effects of Verapamil and Nifedipine in Patients on Propranolol

MICHAEL D. WINNIFORD, ROY V. MARKHAM, BRIAN G. FIRTH, PASCAL NICOD, and L. DAVID HILLIS

The acute effects of intravenous verapamil (0.15 mg/kg to a maximum of 10 mg) or sublingual nifedipine (10 mg) were assessed in patients receiving oral propranolol (234 ± 230 mg/day, mean ± standard deviation). Cardiac output was unchanged by verapamil but increased with nifedipine. Left ventricular dP/dt was reduced only by

*Cardioprotective dosage—the dosage recommended in the Prescribing Information to reduce the risk of reinfarction or cardiovascular mortality for stabilized patients who have survived the acute phase of an MI

you prescribe

is

βBLOCADREN

(TIMOLOL MALEATE | MSD)

Only BLOCADREN is presently indicated for the post-MI patient to reduce the risk of reinfarction, and BLOCADREN is the only beta blocker whose dosage has been established through extensive clinical trials to be the same for post-MI as for initial therapy in hypertension. In hypertension the starting dosage is only 10 mg b.i.d. There is only one dosage for prophylactic use in stabilized patients surviving the acute phase of an MI: 10 mg b.i.d.

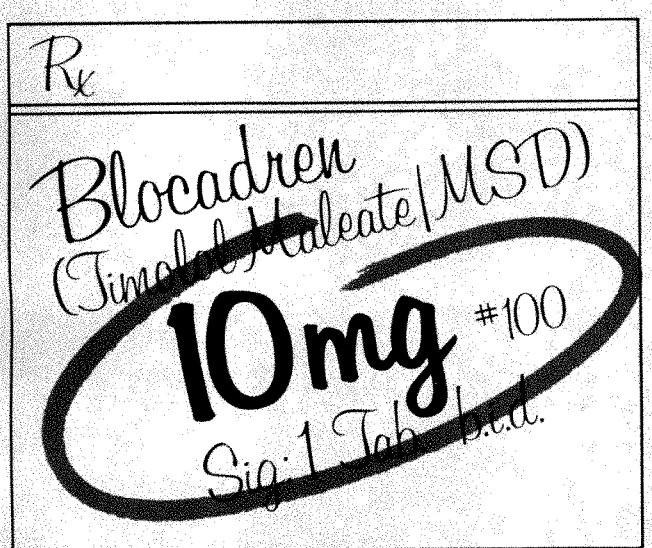
BLOCADREN is contraindicated in patients with: bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be observed closely. If cardiac failure continues, despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disea following Abrupt Withdrawal— Hypersensitivity to catecholamines ha been observed in patients withdrawn from beta-blocker therapy; exacerbatic of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronica administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of on to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and othe measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

for initial therapy in hypertensive patients



Usual dosage range:
10 to 20 mg b.i.d.

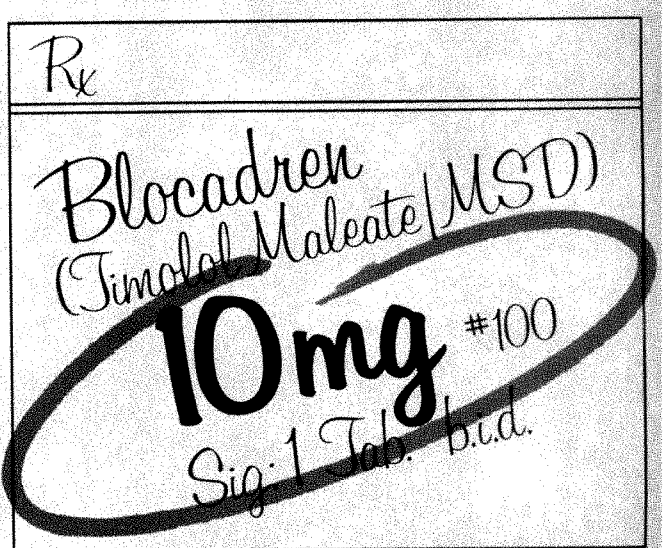
Maximum dosage:
30 mg b.i.d.

There should be an interval of at least seven days between increases in dosages.

Also available:
20-mg tablets

NOTE: IN HYPERTENSION
BLOCADREN may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

for reducing the risk of reinfarction in stabilized post-MI patients



Dosage:
10 mg b.i.d.

Treatment should be initiated within 1 to 4 weeks after infarction.

Data are not available as to whether benefit would ensue if initiated later.

MSD
MERCK SHARP & DOHME

Copyright © Merck & Co., Inc., 1982

BLOCADREN®
(TIMOLOL MALEATE | MSD)

only 10 mg b.i.d.
for initial therapy in hypertension and post-MI

For a Brief Summary of Prescribing Information, please see next page.

BLOCADREN
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction*		Withdrawal†	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

*When an adverse reaction recurred in a patient, it is listed only once.

†Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

verapamil. Verapamil reduced the heart rate and increased A-H intervals; in contrast, nifedipine increased heart rate but did not change the A-H interval. The left ventricular ejection fraction was unaltered by verapamil but increased with nifedipine. Thus, when given to patients receiving propranolol, nifedipine improves cardiac output and left ventricular ejection fraction without affecting atrioventricular conduction, whereas verapamil diminished left ventricular contractility and slows atrioventricular conduction. A propranolol-verapamil combination must be used carefully in patients with underlying left ventricular dysfunction or conduction system disease.

711 Long-Term Follow-Up of Verapamil and Nitrate Treatment for Coronary Artery Spasm

S. BENEDICT FREEDMAN, DAVID R. RICHMOND, and DAVID T. KELLY

Thirty-seven patients with coronary artery spasm without significant atherosclerosis were followed-up for a mean of 21 months after the start of verapamil therapy. All had angina at rest, 32 had nocturnal angina, and 13 had a positive exercise test with S-T elevation. Ten had serious arrhythmias, causing syncope in 7. At last review 27 continued on verapamil, 4 nonresponders to verapamil were taking nifedipine, and 16 were taking additional isosorbide dinitrate. Of the 31 on therapy, 21 were asymptomatic and 9 had improved. Six had stopped therapy, 5 of whom remained asymptomatic. Continuation of smoking was positively associated with recurrence of angina on withdrawal of treatment. Long-term treatment of coronary artery spasm with verapamil or nifedipine and isosorbide dinitrate was well tolerated and angina was relieved completely or attacks were markedly reduced. No documented serious arrhythmia, syncopal episodes, myocardial infarction, or death occurred during follow-up.

716 Pharmacokinetics of Verapamil: Experience With a Sustained Intravenous Infusion Regimen

MICHAEL J. REITER, DAVID G. SHAND, LINDA M. AANONSEN, ROBERT WAGONER, ELIZABETH McCARTHY, and EDWARD L. C. PRITCHETT

From the disappearance kinetics of a single intravenous dose of verapamil administered to 9 subjects, a 3 stage intravenous infusion regimen of verapamil was designed to rapidly achieve and maintain a constant plasma verapamil concentration. The regimen consisted of a loading bolus (10 mg over 2 minutes), followed by a 30 minute loading infusion (0.375 mg/min), and finally a maintenance infusion (0.125 mg/min). This regimen was tested in 7 subjects during sinus rhythm for 2 to 12 hours. Maintenance plasma concentration averaged 122 ng/ml and was associated with stable prolongation of the P-R interval, transient and slight decreases in blood pressure and sinus cycle length, and no significant side effects.

722 Variability of Response to Beta-Receptor Blockade for Angina Pectoris in Clinical Trials: A Study of Pindolol

WILLIAM E. HARSTON and GOTTLIEB C. FRIESINGER

Pindolol produced a significant decrease in the double-product and improvement in exercise tolerance in patients with angina pectoris. However, when the same patients were evaluated in a long-term crossover study, there was no clinical improvement over placebo. Patients on placebo had a gradual improvement in exercise tolerance, possibly due to a training effect. Individual patient response to pindolol varied, with some showing clinical improvement and some no improvement despite similar reductions in double-product. Angina occurred at a lower double-product with exercise, suggesting that beta blockade adversely affected other variables of myocardial oxygen demand or decreased coronary blood supply. This study illustrates the difficulties with patient variability and study design that are encountered in studies of beta-blocking agents for angina pectoris.

728 Antiarrhythmic, Antifibrillatory, and Hemodynamic Actions of Bethanidine Sulfate: An Orally Effective Analog of Bretylium for Suppression of Ventricular Tachyarrhythmia

MARVIN B. BACANER and DAVID G. BENDITT

Bethanidine sulfate is a chemical and pharmacologic analog of bretylium tosylate that has virtually identical antifibrillatory and inotropic actions on the heart. Bretylium is the only drug approved by the Food and Drug Administration specifically for the "prophylaxis and treatment of ventricular fibrillation." Unlike bretylium, which is poorly absorbed from the gut and limited to parenteral use, oral bethanidine is absorbed rapidly. Bethanidine was given to 23 patients with recurrent multiple drug refractory ventricular tachycardia and fibrillation. Eighteen patients (78%) had complete suppression of spontaneous or electrophysiologically inducible tachyarrhythmia; 3 patients were improved and 2 had no benefit. In 6 of 9 patients studied by programmed electrophysiologic drug testing, bethanidine completely prevented previously inducible ventricular tachyarrhythmia at the maximal stimulus tested (including 4 extrastimuli and burst-pacing at 10 times threshold). Cardiac output measured in 6 pa-

Continued on Page A32

tients 1 to 2 hours after bethanidine was increased in 4, unchanged in 2, and decreased in 1. Ten patients on long-term therapy with bethanidine and protriptylene (to prevent orthostatic hypotension) have been free of arrhythmia 2 to 26 months.

735 **Continuous Monitoring of Left Ventricular Performance With the Computerized Nuclear Probe During Laryngoscopy and Intubation Before Coronary Artery Bypass Surgery**

ROBERT W. GILES, HARVEY J. BERGER, PAUL G. BARASH, SANJIWAN TARABADKAR, PETER G. MARX, GRAEME L. HAMMOND, ALEXANDER S. GEHA, HILLEL LAKS, and BARRY L. ZARET

Left ventricular performance was monitored serially in 25 patients during laryngoscopy and intubation in the anesthetic induction period before elective coronary artery bypass surgery using the labeled equilibrium blood pool and the computerized nuclear probe. All patients had an immediate decrease in left ventricular ejection fraction accompanying reflex hypertension, and tachycardia during laryngoscopy and endotracheal intubation. The left ventricular ejection fraction was significantly decreased for 3 minutes. Seven patients had no recovery of left ventricular ejection fraction compared with the preintubation value. Ten healthy noncardiac patients undergoing orthopedic surgery had a similar decrease in ejection fraction, but of shorter duration. This study demonstrates that profound decreases in left ventricular performance accompany reflex hypertension and tachycardia occurring during endotracheal intubation, and that some patients with coronary artery disease have a persistent decrease in left ventricular function.

744 **Constrictive Pericarditis as a Complication of Cardiac Surgery: Recognition of an Entity**

MICHAEL A. KUTCHER, SPENCER B. KING III, BENJAMIN N. ALIMURUNG, JOSEPH M. CARVER, and R. BRUCE LOGUE

Eleven patients in whom constrictive pericarditis developed after cardiac surgery are reported on (incidence 0.21%). The pericardium had been left open in all cases. The average time to presentation of pericardial constriction was 82 days after surgery (range 14 to 186). The diagnosis was suspected on clinical and echocardiographic grounds, and confirmed by cardiac catheterization. Three patients eventually responded to medical therapy. Eight patients required a radical pericardiectomy. Constrictive pericarditis may develop as a complication of cardiac surgery in spite of an open pericardium. This entity should be considered in postoperative patients who present with deteriorating cardiac function.

749 **Increased Physical Activity: A Protective Factor Against Heart Attacks in Puerto Rico**

MARIO R. GARCIA-PALMIERI, RAUL COSTAS, Jr., MERCEDES CRUZ-VIDAL, PAUL D. SORLIE, and RICHARD J. HAVLIK

The incidence and potential risk factors of coronary heart disease were assessed in 2,585 rural and 6,208 urban men, aged 45 to 64 years, participating in the Puerto Rico Heart Health Program, a prospective epidemiologic study of coronary heart disease initiated in 1965. An index of daily physical activity and a metabolic equivalent of heaviest activity were estimated from each individual history. Rural men had higher mean levels of overall activity as well as higher levels of heavy activity than urban men. An 8¼ year follow-up study for coronary heart disease other than angina pectoris was analyzed for relationships with physical activity. Significant inverse associations were found for both urban and rural men. Although the physical activity index was inversely associated with most known coronary risk factors, multivariate analyses indicated a significant independent inverse relation with the incidence of coronary heart disease. In Puerto Rico, increased physical activity appears to be a separate protective factor against heart attack.

756 **Inter- and Intraatrial Dissociation During Spontaneous Atrial Flutter: Evidence for a Focal Origin of the Arrhythmia**

PETER L. FRIEDMAN, PEDRO BRUGADA, KARL-HEINZ KUCK, DENIS ROY, JERONIMO FARRE, FRITS W. H. M. BÄR, and HEIN J. J. WELLENS

Electrophysiologic studies in 2 patients with atrial flutter provide evidence that this arrhythmia may be focal in origin, arising in a relatively small area of atrial myocardium. In 1 patient a burst of rapid atrial pacing during atrial flutter precipitated atrial fibrillation in several regions of the atria, while typical atrial flutter persisted in other regions. In another patient a pattern of 3:2 Wenckebach conduction was noted between the left and right atria during atrial flutter. Whether due to focal reentry or triggered automaticity, atrial flutter may be present in some parts of the atria and not others and may even be inapparent in the surface electrocardiogram.

Blood Pressure Monitor

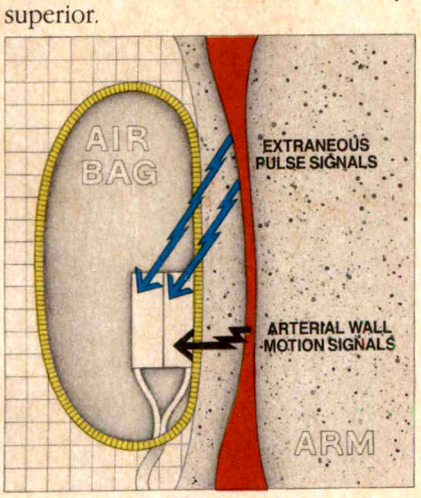
Why no other automatic blood pressure monitor measures up to Kendall.

Introducing the Kendall blood pressure monitor: a safer, more accurate, more convenient way to measure blood pressure.

The Kendall blood pressure monitor is a major advance in automatic blood pressure monitoring.

Compare it to any other unit available today, and we believe there's only one conclusion you can reach:

In terms of accuracy, safety, reliability and ease of use, the Kendall model 8200 monitor is demonstrably superior.

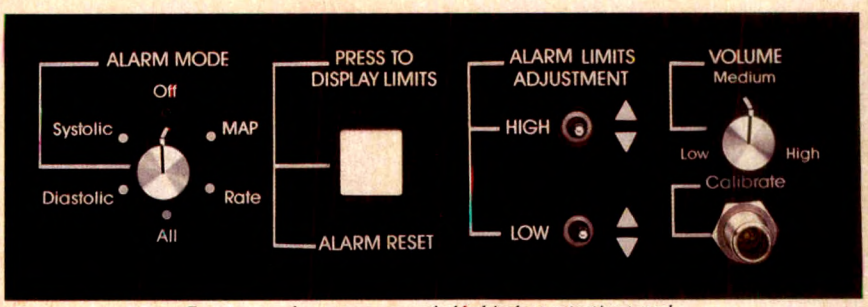


A unique dual-headed sensor isolates signals produced by systolic and diastolic pressures.

Measurements based on actual information.

The Kendall monitor provides a new level of accuracy in automatic blood pressure monitoring. The reason —our differential sensor technique.

Mounted in our cuff is a sophisticated dual-headed sensor. This pressure-sensitive device factors out many extraneous signals, and reports those signals *directly* associated with systolic and diastolic pressures.



Easy to use alarms are concealed behind a protective panel.

Readings are based on actual information—not on estimating techniques. The result is state-of-the-art accuracy that goes a step further than the standard oscillometric technique.

A unit as reliable as it is accurate.

In critical care situations, the reliability of a piece of equipment is an absolute necessity. Here are some of the ways the Kendall blood pressure monitor satisfies this objective:

The unit automatically self-calibrates between readings to account for drifts and variations in temperature. It has a 16-bit microcomputer that provides enhanced ability to qualify data. The monitor is designed to meet UL 544.

Every safety and convenience feature you can think of. And then some.

The Kendall blood pressure monitor puts patient safety first.

The unit is programmed to deflate automatically in the presence of abnormal motion, or if time or pressure exceeds specified limits. In the automatic mode, it enforces a 15-second delay to allow for venous return. And it has a manual stop button that allows you to instantly interrupt the cycle.

The unit has comprehensive visual and audible alarm capabilities. You can alarm any one or all four parameters.

Other important safety and convenience features include:

- Easy to read numerical displays.
- Automatic time cycling.
- A port for attaching to a manual sphygmomanometer.
- Electrical isolation between sensor and patient.
- A hard-copy printer option.

There's so much more we'd like you to know.

If you'll send us the coupon below, we'll arrange for an evaluation of the Kendall blood pressure monitor.

By any measure you choose, you'll find that no other automatic blood pressure monitor measures up to it.

I'd like to find out more about the Kendall blood pressure monitor.

INNOVATORS IN PATIENT CARE

HM-2613Y

MICROENCAPSULATION:

Liquid potassium release from micro-encapsulated KCl crystals, and a special dispersing agent to minimize the likelihood of high local concentrations. Plus the solid convenience of a taste-free capsule, to promote long-term compliance.

THAT'S MICRO-K®*
(Potassium Chloride)

*For patients who cannot tolerate or refuse to take liquid preparations.

The potassium supplement you can prescribe with confidence.

DISPERSION

1. Convenient taste-free capsule dissolves, releasing 10,000 individually coated KCl crystals.

2. Unique dispersing agent spreads these microcapsules throughout the G.I. tract, minimizing likelihood of ulceration due to high localized concentrations. *(Please see Warnings and Contraindications sections of prescribing information.)*

LIQUID POTASSIUM RELEASE PLUS SOLID DOSAGE BENEFITS

A SUPERIOR KCl DELIVERY SYSTEM

DIFFUSION

3. Liquid-permeable coating around each individual crystal protects mucosa from contact with solid potassium.

4. Diffusion of liquid KCl with controlled 8-10 hour release begins when gastrointestinal fluid permeates coating to dissolve KCl crystal inside.

5. Pharmacologically inert coating is excreted.

Artist's rendering of Micro-K dispersion in G.I. tract.

LIQUID POTASSIUM RELEASE PLUS SOLID DOSAGE BENEFITS

MICRO-K®
(Potassium Chloride)
Controlled-Release Extencaps® 8 mEq

- Convenient taste-free capsule
- 10,000 individually coated crystals
- Special dispersing agent, to minimize high local concentrations
- Diffusion of liquid KCl over 8-10 hours

Prescribing Information

Description: Micro-K Extencaps are hard gelatin capsules, each containing 600 mg of dispersible small crystalline particles of potassium chloride (equivalent to 8 mEq K). Each particle is microencapsulated with a polymeric coating which allows for controlled release of potassium and chloride ions over an eight- to ten-hour period. The dispersibility of the microcapsules and the controlled release of ions are intended to minimize the likelihood of high localized concentrations of potassium chloride and resultant mucosal ulceration within the gastrointestinal tract.

The polymeric coating forming the microcapsules functions as a water-permeable membrane. Fluids pass through the membrane and gradually dissolve the potassium chloride within the microcapsules. The resulting potassium chloride solution slowly diffuses outward through the membrane.

Actions: Potassium ion is the principal intracellular cation of most body tissues. Potassium ions participate in a number of essential physiological processes, including the maintenance of intracellular tonicity, the transmission of nerve impulses, the contraction of cardiac, skeletal, and smooth muscle and the maintenance of normal renal function.

Potassium depletion may occur whenever the rate of potassium loss through renal excretion and/or loss from the gastrointestinal tract exceeds the rate of potassium intake. Such depletion usually develops slowly as a consequence of prolonged therapy with oral diuretics, primary or secondary hyperaldosteronism, diabetic ketoacidosis, severe diarrhea, or inadequate replacement of potassium in patients on prolonged parenteral nutrition. Potassium depletion due to these causes is usually accompanied by a concomitant deficiency of chloride and is manifested by hypokalemia and metabolic alkalosis. Potassium depletion may produce weakness, fatigue, disturbances of cardiac rhythm (primarily ectopic beats), prominent U-waves in the electrocardiogram, and in advanced cases, flaccid paralysis and/or impaired ability to concentrate urine.

Potassium depletion associated with metabolic alkalosis is managed by correcting the fundamental causes of the deficiency whenever possible and administering supplemental potassium chloride, in the form of high potassium food or potassium chloride solution, capsules or tablets. In rare circumstances (e.g., patients with renal tubular acidosis) potassium depletion may be associated with metabolic acidosis and hyperchloremia. In such patients potassium replacement should be accomplished with potassium salts other than the chloride, such as potassium bicarbonate, potassium citrate, or potassium acetate.

INDICATIONS: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases, supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: *Hyperkalemia.* In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.

The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustments.

Interaction with Potassium-Sparing Diuretics. Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions. Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths, in addition to upper gastrointestinal bleeding. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation.

Micro-K Extencaps contain microcapsules which disperse upon dissolution of the hard gelatin capsule. The microcapsules are formulated to provide a controlled release of potassium chloride. The dispersibility of the microcapsules and the controlled release of ions from the microcapsules are intended to minimize the possibility of a high local concentration near the gastrointestinal mucosa and the ability of the KCl to cause stenosis or ulceration. Other means of accomplishing this (e.g., incorporation of KCl into a wax matrix) have reduced the frequency of such lesions to less than one per 100,000 patient years (compared to 40–50 per 100,000 patient years with enteric-coated KCl), but have not eliminated them. The frequency of GI lesions with Micro-K Extencaps is, at present, unknown. Micro-K Extencaps should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis. Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and may be minimized by taking the dose with meals or by reducing the dose.

Intestinal bleeding, ulceration, perforation and obstruction have been reported in patients treated with solid dosage forms of potassium salts and may occur with Micro-K Extencaps (see Contraindications and Warnings).

One of the most severe adverse effects of potassium supplementation is hyperkalemia (see Contraindications, Warnings, and Overdosage).

Skin rash has been reported rarely with potassium preparations.

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiogram changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following: (1) elimination of foods and medications containing potassium and of potassium-sparing diuretics; (2) intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10–20 units of insulin per 1,000 ml; (3) correction of acidosis, if present, with intravenous sodium bicarbonate; (4) use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Dosage and Administration: The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient, but typically is in the range of 2 to 3 Micro-K Extencaps per day (16 to 24 mEq K) for the prevention of hypokalemia and 5 to 12 Micro-K Extencaps (40 to 96 mEq K) or more per day for the treatment of potassium depletion. If more than 2 Micro-K Extencaps are prescribed per day, the total daily dosage should be divided into two or more separate doses.

How Supplied: Pale orange capsules (Extencaps), each containing 600 mg microencapsulated potassium chloride (equivalent to 8 mEq K) in bottles of 100 (NDC 0031-5720-63), and 500 (NDC 0031-5720-70) and Dis-Co® unit dose packs of 100 (NDC 0031-5720-64).

Animal Toxicology: The ulcerogenic potential of microencapsulated KCl was studied in anesthetized cats by direct applications on exteriorized gastric mucosa. The microcapsules of KCl were found to be non-ulcerogenic and significantly less irritating than wax-matrix tablets and 20% solution of KCl.

In groups of monkeys (up to 8 monkeys per group) receiving different formulations of potassium chloride at equivalent daily dosage (2400 mg KCl) for four and one-half days, Micro-K Extencaps showed no tendency to cause intestinal ulceration (similar to liquid KCl and a wax-matrix preparation but in contrast to an enteric-coated KCl tablet) and minimal gastric irritation (less than a wax-matrix preparation).

762 **Echocardiographic Features of Carcinoid Heart Disease**

JOHN A. CALLAHAN, EDMUND M. WROBLEWSKI, GUY S. REEDER, WILLIAM D. EDWARDS, JAMES B. SEWARD, and ABDUL J. TAJIK

The records of the Mayo Clinic patients with known carcinoid syndrome in whom echocardiographic studies had been done were reviewed. Nineteen patients had M-mode and 2-dimensional echocardiographic examinations, and 1 patient had an M-mode examination only. Of the 20 patients, 8 had no evidence by echocardiogram of carcinoid heart disease; 2 had changes in the tricuspid valve echogram suggestive of early carcinoid heart disease, and the other 10 patients had the following distinctive echocardiographic findings: (1) a pattern of right ventricular volume overload (enlarged right ventricle with abnormal septal motion); (2) abnormal right-sided valves, including (a) a striking appearance of the tricuspid valve, the leaflets appearing thickened, retracted, and fixed in a semiopen position throughout the cardiac cycle, and (b) thickened, retracted pulmonary cusp valves, when visualized; and (3) the left-sided valves and chambers rarely involved. These echocardiographic features are distinctive of advanced carcinoid heart disease and correlate closely with pathologic findings.

PEDIATRIC CARDIOLOGY

769 **Exercise Electrocardiogram, Blood Pressure, and Working Capacity in Young Patients With Valvular or Discrete Subvalvular Aortic Stenosis**

FREDERICK W. JAMES, DAVID C. SCHWARTZ, SAMUEL KAPLAN, and STEVE P. SPILKIN

Electrocardiographic changes, blood pressure, and working capacity (total work) were recorded during an upright cycle exercise test in 65 children and young adults with valvular or discrete subvalvular aortic stenosis. Exercise-induced S-T depression increased in frequency and amplitude with increasing pressure gradient across the left ventricular outflow tract. Mean total work and peak exercise systolic pressure were significantly lower in the patients than in control subjects. An exercise profile consisting of S-T depression of 2 mm or more and markedly decreased total work and exercise systolic pressure was characteristic of patients with a resting left ventricular-aortic systolic gradient of 70 mm Hg or greater. At least 2 or more components of this exercise profile occurred in 20% of patients with a gradient less than 70 mm Hg. Exercise testing reveals serious abnormalities in patients otherwise classified as having trivial or moderate aortic stenosis.

776 **Mechanism of Acquired Right Ventricular Outflow Tract Obstruction in Patients With Ventricular Septal Defect: An Angiocardiographic Study**

GIACOMO PONGIGLIONE, ROBERT M. FREEDOM, DAVID COOK, and RICHARD D. ROWE

Right ventricular outflow tract obstruction can complicate the natural history of patients with isolated ventricular septal defect. Although numerous pathologic mechanisms may be responsible for this phenomenon, it is less clear what the frequency is of each of these mechanisms in any cohort of patients studied in a single institution. Twenty patients were identified who had isolated ventricular septal defect from 1970 to 1981 and who acquired a right ventricular outflow tract gradient of 25 mm Hg or greater. They ranged in age at the initial catheterization investigation from 4 days to 23 months and on subsequent study from 13 months to 8 years. Angiographically, 2 mechanisms were implicated in the 20 patients. Hypertrophy of right ventricular anomalous muscle bundles was identified in 19 of the 20 while hypertrophy of a maligned infundibular septum (that is, classic tetralogy type) was identified in only 1 patient. These data indicate that acquired right ventricular outflow tract obstruction is rarely of the classic tetralogy type.

781 **Surgical Repair of Congenitally Corrected Transposition of the Great Arteries: Results and Follow-Up**

BETAU HWANG, FREDERICK BOWMAN, JAMES MALM, and EHUD KRONGRAD

Eighteen patients with congenitally corrected transposition of the great arteries had open heart surgery for repair of intracardiac defects. Fourteen patients (78%) are alive (mean follow-up 4.5 years). Postoperative hemodynamic compromise was directly related to identifiable residual defects such as atrioventricular valve insufficiency, residual septal defect, or pulmonary conduit stenosis. Eight of 18 patients required more than 1 open heart operation. No patient had primary ventricular dysfunction. None of the last 11 patients had complete heart block, but surgical injury to the bundle branches was common. Improved knowledge of the precise location of the atrioventricular conduction system in congenitally corrected transposition resulted in a marked decrease in atrioventricular block. Also, in the absence of postoperative residual defects longevity and quality of life may improve considerably, but many patients may require a second operation.

Medtronic makes unipolar pacemakers that don't listen when pectoral muscles talk

Spectrax SXT™ solves the problem of muscle electrical noise sensing in unipolar pacing.

Your pacemaker patient merely combs his hair, and electrical noise from his pectoral muscles inhibits pacing function. You have reason to be concerned, especially since the patient may experience the symptoms which brought him to you in the first place.

There is a solution: Medtronic.

Medtronic unipolar pacemakers do *not* sense the electrical artifacts typically generated by normal pectoral muscle activity. Our patented sensing circuit design discriminates between typical muscle artifacts and the heart's R-waves.

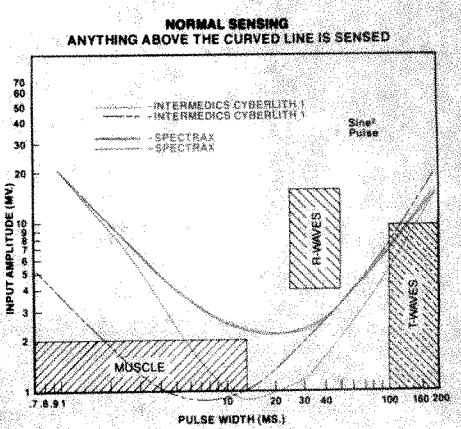
The multiprogrammable Spectrax SXT is one sterling example of how Medtronic design outwits pectoral muscles. Electrograms show that all human musculature "sounds" practically alike, making absolute discrimination very difficult. Opening and closing pacemaker band width is clearly not the solution. Medtronic technology is.

Extensive testing of ten manufacturers' pacemakers demonstrates that Medtronic provides superior muscle EMI rejection[1]. The sensing curve at right demonstrates why.

Spectrax listens only to the heart. And you. Spectrax SXT is Medtronic's most advanced single-chamber pacemaker. It gives you the programming versatility you expect from Spectrax, with the added advantage of telemetry for simple—and just plain useful—follow-up. All in only 45 grams. And you can select from one unipolar or two bi-polar configurations.

Medtronic's integrated pacing system gives you the most versatile patient management. Components are performance-matched for precise and reliable pacing therapy.

While Spectrax SXT tunes out pectoral muscle noise, you keep tuned into the heart through the Medtronic Censys™ programmer, your vital communications link to any Medtronic pacemaker. With the Spectrax SXT, Censys transmits eight programmed parameters, battery status and ID numbers. Plus intracardiac electrograms which could alert you to adjust sensitivity settings. Several other programmable features provide simplified, precise follow-up. And you have the easy-to-read ECGs and other advantages of unipolar pacing, with the assurance that muscle EMI will not threaten your patient's new feeling of well being. Spectrax SXT™—The world's most prescribed pacemaker.



Medtronic

Leading the way to man's heart.

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by

William C. Roberts, M.D.
Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health; and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

__ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

786 Left and Right Ventricular Adaptation to Right Ventricular Overload Before and After Surgical Repa of Tetralogy of Fallot

PETER E. LANGE, DIETRICH G. W. ONNASCH, ALEXANDER BERNHARD, and PAUL H. HEINTZEN

Angiographic volume data were obtained for the left (n = 43) and the right (n = 56) ventricle in tetralogy of F before and after surgical repair. The preoperatively decreased ($p < 0.01$) left ventricular ejection fraction di improve postoperatively, even if excellent results were achieved. A certain functional reserve, however pears to be preserved, since the ejection fraction did not decrease further with increasing volume loads d a residual ventricular septal defect. Postoperatively the right ventricular ejection fraction was reduced si cantly ($p < 0.01$) compared with normal even without significant outflow tract obstruction or additional vo load. The further decrease in ejection fraction with increasing volume loads due to pulmonary insufficienc sidual ventricular septal defect, or both suggests a loss of functional reserve. Attempts to minimize right ve ular volume load after surgical repair of tetralogy of Fallot appear advisable.

795 Early Assessment of Hemodynamic Status After Repair of Tetralogy of Fallot: A Comparison of 24 Hour (Intensive Care Unit) and 1 Year Postoperative Data in 98 Patients

PETER LANG, CARL W. CHIPMAN, HAROLD SIDEN, ROBERTA G. WILLIAMS, WILLIAM I. NORWOOD, and ALDO R. CASTANEDA

Hemodynamic data obtained in the intensive care unit, immediately after repair of tetralogy of Fallot, were pared with measurements obtained at 1 year postoperative catheterization in 98 infants and children. Inte care unit measurement of pulmonary arterial oxygen saturation is valuable for determining the presence c sence of significant left-to-right shunts after repair of tetralogy of Fallot and should be considered an adjur patient management. Intensive care unit measurement of right ventricular outflow tract gradient identifie tients with a significant gradient but is not highly sensitive.

800 Pediatric Cardiac Catheterization With Same-Day Discharge

J. DEANE WALDMAN, TERRANCE S. YOUNG, STANLEY J. PAPPELBAUM, SEARLE W. TURNER, STANLEY E. KIRKPATRICK, and LILY M. GEORGE

Experience with cardiac catheterization in 233 children without overnight hospital stay (same-day disch was evaluated. In 232 children, no problems occurred after hospital discharge; 1 child required readmissi psoas tendinitis after retrograde aortography. Same-day discharge was safely applied regardless of age, di sis, systemic heparinization, use of large-bore sheaths, retrograde arterial catheterization, or cineangiogr Hospital costs were reduced 29% compared with the standard 42 hour stay. Same-day discharge offers th lowing advantages: (1) improved medical care, (2) reduced medical costs, and (3) elimination of time-pre in training and teaching as well as therapeutic decision-making. Critical factors in success are coordinat multiple health care professionals and physician judgment of the patient's clinical status. We speculate reassessment of other hospital-oriented procedures may foster the development of methods to improve m care, reduce cost, or both.

804 Compression of Intrapulmonary Bronchi by Abnormally Branching Pulmonary Arteries Associated With Absent Pulmonary Valves

MARLENE RABINOVITCH, STAFFORD GRADY, IVAN DAVID, RICHARD VAN PRAAGH, URSULA SAUER, KONRAD BUHLMEYER, ALDO R. CASTANEDA, and LYNNE REID *with the technical assistance of* DONNA K. SILVA

In 3 patients with absent pulmonary valve syndrome and absent ductus arteriosis, the lungs were injecte analyzed postmortem using morphometric techniques. Two patients had tetralogy of Fallot and 1 had D-tra sition of the great arteries, the latter being the first autopsy-proved case of absent pulmonary valve with tra sition. In addition to the expected dilatation of the central pulmonary arteries and compression of the mai bronchi, postmortem pulmonary artery arteriography revealed a bizarre pattern of hilar branching. Instead gle segmental arteries, tufts of arteries arose which entwined and compressed the intrapulmonary bron 1 case the number of bronchial generations was decreased and in 1 other case alveolar multiplication w verely impaired. Our data may therefore explain why, in some patients with absent pulmonary valve sync relief of compression of the mainstem bronchus alone does not appreciably alleviate or reverse severe re tory disease.

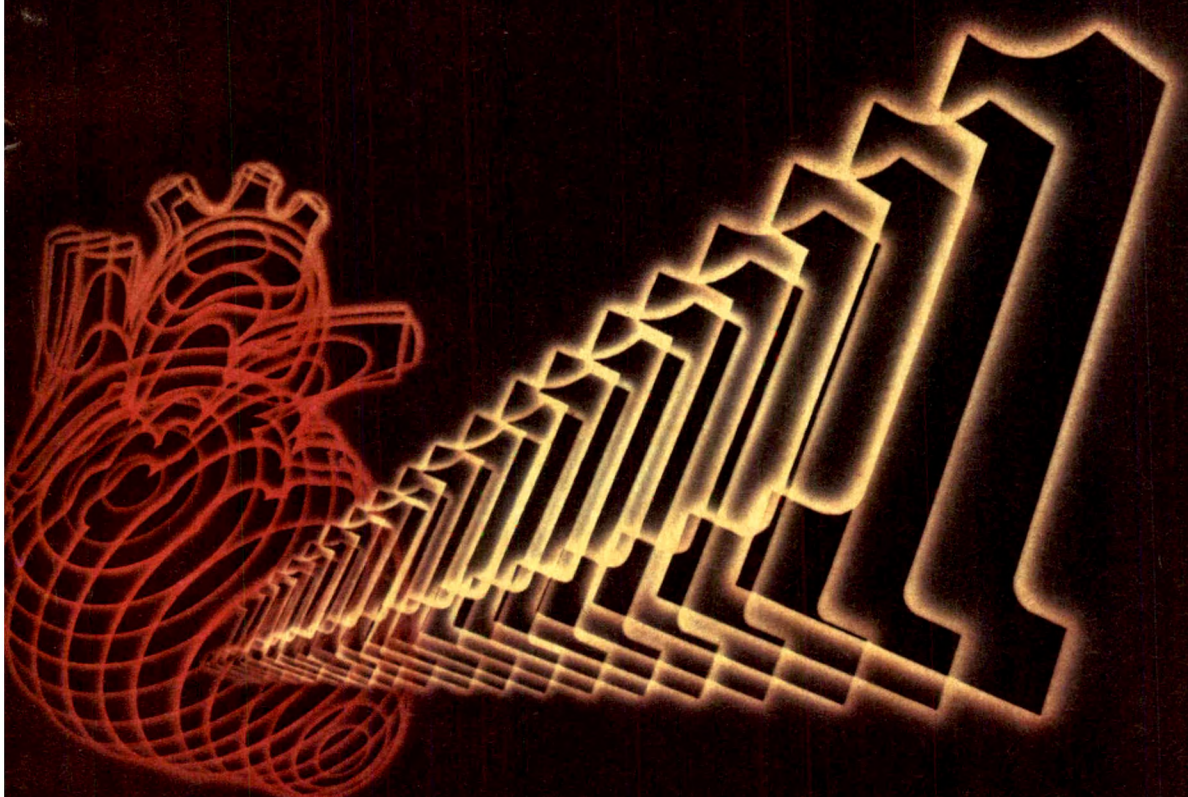
Only one beta-blocker provides once-a-day round-the-clock protection in both hypertension and angina pectoris.

CORGARD®
[nadolol tablets]
IS THE ONE



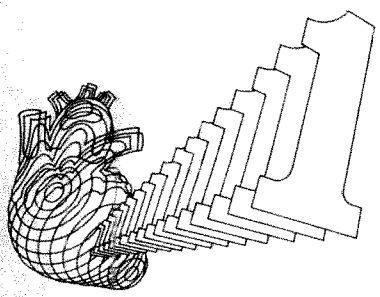
Reliable 24-hour beta blockade at all titrated dosages

SQUIBB®

Innovators in cardiovascular medicine

See next page for brief summary.

The only once-a-day beta-blocker for both hypertension and angina pectoris



CORGARD®
nadolol tablets
40 mg, 80 mg, 120 mg, 160 mg scored tablets

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of beta$_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a beta$_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval — see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

SQUIBB®

© 1982 E.R. Squibb & Sons, Inc. Issued January 1982 512-501

Visit us at The AHA. And see why we're called Pacesetter.

uring the American Heart Association Sessions, we'll both have a special pportunity. You, to participate in our stimulating scientific forums and reakfast discussions. Us, to show off our latest technological innovations.

Ve've set the pace for our industry for years, and we're at it again. partial preview:

nnovation:

- Programalith® III, our smallest multiprogrammable, single- and dual-chamber pacemaker with expanded telemetry.
- AFP,™ with multiprogrammable DDD pacing and with telemetry of stored, measured and physiologic wave form data.
- The new Model 388 Telemetry System, providing multiprogrammability and expanded telemetry for all Programalith series pacers.
- New *"Fast Pass"*™ unipolar and bipolar silicone rubber leads with a special coating, smaller diameters and excellent handling characteristics.

cientific Forums:

n all-new exhibit with a special built-in theatre, where we'll be covering:

- Intracardiac Event Recording;
- Pharmaceutical Infusion Systems;
- Pacing Systems with Surface and Endocardial EKG Telemetry Capabilities;
- Clinical Experience with DDD Pacing;
- And more!

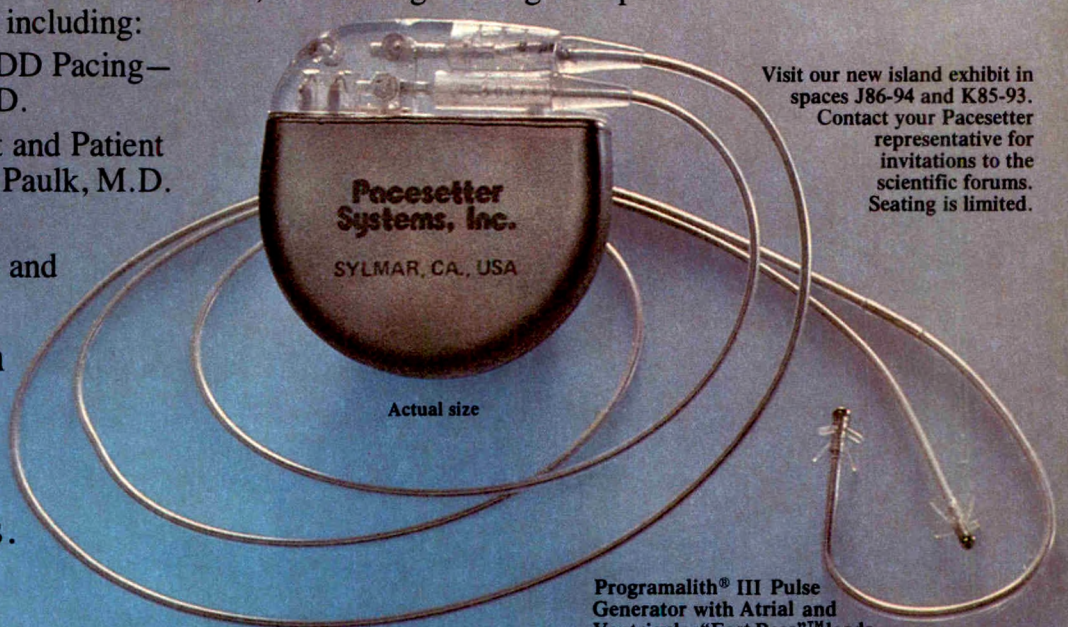
reakfast Discussions:

Ionday and Tuesday, November 15 and 16, two distinguished guest speakers will discuss various spects of DDD pacing, including:

- Hemodynamics of DDD Pacing— Charles L. Byrd, M.D.
- Clinical Management and Patient Follow-up — E. Alan Paulk, M.D.

ontact your Pacesetter presentative for details and vitations.

lan on visiting with s. You'll see why ur whole industry ow knows who he real Pace*setter* is.



Actual size

Visit our new island exhibit in spaces J86-94 and K85-93. Contact your Pacesetter representative for invitations to the scientific forums. Seating is limited.

814 Two-Dimensional Echocardiographic Identification of Pulmonary Artery Branch Stenosis

DAVID D. TINKER, NAVIN C. NANDA, J. PETER HARRIS, and JAMES A. MANNING

The use of real-time, 2-dimensional echocardiography in the detection of pulmonary artery stenosis is described in 10 patients with congenital heart disease, all of whom had angiographically documented pulmonary artery stenosis. The merits of various transducer positions in detecting this lesion and the difficulties associated with diagnosing pulmonary branch stenosis by echocardiography are discussed.

EXPERIMENTAL STUDIES

821 Ventricular Performance and Biochemical Alteration of Regional Ischemic Myocardium After Reperfusion in the Pig

MARVIN L. MURPHY, CHUN FU PENG, JAMES J. KANE, and KARL D. STRAUB

This study, using an animal model, evaluates regional left ventricular wall thickness, analyzes metabolic and biochemical changes, and examines tissue hemorrhage during 15, 30, and 120 minutes of myocardial ischemia, each followed by 120 minutes of reperfusion. Reperfusion after 15 minutes of ischemia showed nearly normal ventricular wall thickening and motion, intact metabolic and biochemical function, and no tissue hemorrhage. However, reperfusion after 30 and 120 minutes of ischemia was associated with ventricular wall thickening and failure to resume systolic and diastolic wall motion. Furthermore, adverse metabolic and biochemical alterations and myocardial hemorrhaging increased with the duration of ischemia. These findings suggest critical myocardial damage occurring between 15 and 30 minutes of ischemia in an animal model without preexisting coronary collateral circulation. The observed metabolic and biochemical changes are consistent with irreversible cell membrane defects allowing Ca^{2+} accumulation and adversely affecting diastolic relaxation and systolic thickening.

829 Effect of Intraaortic Balloon Counterpulsation on Regional Myocardial Blood Flow and Oxygen Consumption in the Presence of Coronary Artery Stenosis: Observations in an Awake Animal Model

HENRY GEWIRTZ, WILLIAM OHLEY, DAVID O. WILLIAMS, YING SUN, and ALBERT S. MOST

In this study the mechanism by which arterial counterpulsation relieves myocardial ischemia in patients with unstable angina pectoris was examined. Studies were conducted in closed-chest conscious pigs instrumented with severe (82% reduction in luminal diameter) coronary artery stenosis. Hemodynamics, regional myocardial blood flow (microspheres), and oxygen consumption were measured at control, after 15 to 20 minutes of intraaortic balloon pumping, and at second control. In response to pumping, there was no change (versus control) in endocardial blood flow distal to the stenosis. Epicardial flow and myocardial oxygen consumption distal to the stenosis decreased in response to intraaortic balloon pumping. The data support the hypothesis that intraortic balloon pumping relieves myocardial ischemia in patients with unstable angina pectoris primarily by reducing myocardial oxygen demand rather than by increasing oxygen supply.

838 Detection of Ischemic Myocardium in Vivo Through the Chest Wall by Quantitative Ultrasonic Tissue Characterization

RANDOLPH D. COHEN, JACK G. MOTTLEY, JAMES G. MILLER, PETER B. KURNICK, and BURTON E. SOBEL

Quantitative analysis of ultrasound is potentially valuable for noninvasive differentiation of specific types of cardiac disease, if the effects of intervening tissue can be compensated for. Accordingly, to characterize the quantitative effects of the chest wall on ultrasonic signal backscattered by ischemic and normal myocardium, frequency-dependent backscatter was measured in dogs both through the closed chest and with the chest open, directly from the myocardium. Closed-chest and open-chest measurements were repeated after ligation of the left anterior descending coronary artery. Closed-chest data were compensated by correcting for the average slope of the attenuation-frequency function of chest wall. Compensated closed-chest measurements correlated with epicardial measurements. Differentiation of normal from ischemic myocardium was achieved with both closed- and open-chest measurements ($p < 0.005$). These results suggest that tissue characterization through the chest wall may be a practical approach for noninvasive detection of intrinsic properties of normal and diseased myocardium.

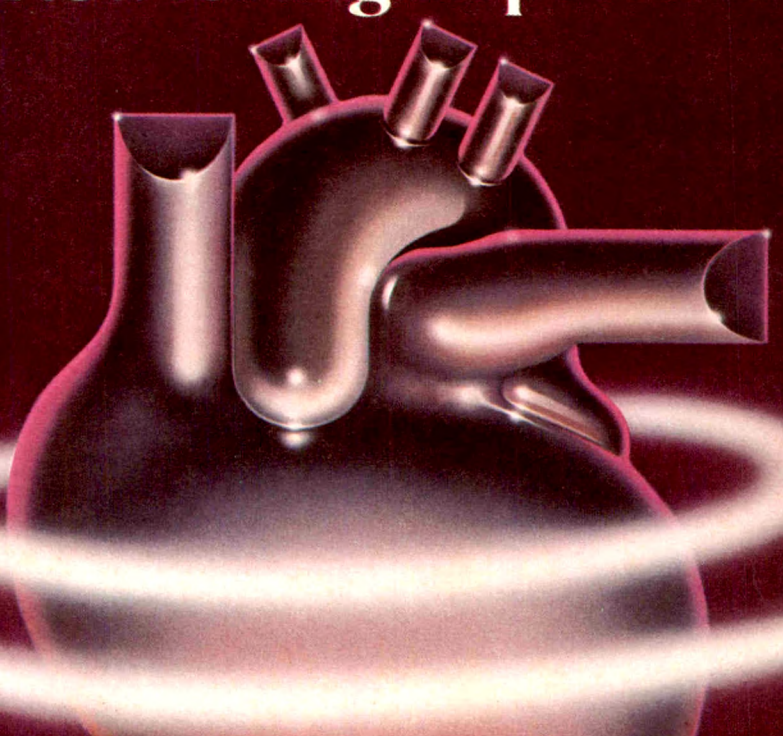
The first calcium antagonist introduced into American medicine...

Now in oral form. Now for angina pectoris.



Now for angina pectoris

ISOPTIN® TABLETS (verapamil HCl/Knoll)

In angina of effort:

Isoptin decreases myocardial oxygen demand and improves exercise tolerance

By decreasing peripheral vascular resistance and decreasing cardiac afterload, Isoptin decreases the workload of the heart and the amount of oxygen consumed by the myocardium. This action accounts for the significant improvement in exercise tolerance and reduction in angina attacks that Isoptin produces in patients with classic angina of effort.

An agent with two major antianginal actions

In angina at rest:

Isoptin dilates the coronary arteries and prevents coronary vasospasm

While beta blockers may cause coronary vasoconstriction, Isoptin has been shown to prevent spasm and to dilate both normal and atherosclerotic coronary arteries. This action accounts for the significant reduction in the frequency of both anginal attacks and ischemic ECG events that Isoptin produces in patients with unstable (preinfarction, crescendo) or Prinzmetal's angina.

Isoptin has proved highly effective in all forms of angina.

In double-blind, crossover studies of angina of effort, patients exercised significantly longer when on Isoptin than on propranolol—42–72% longer on Isoptin (360–480 mg/day) and 30–42% longer on propranolol (240–320 mg/day), compared to placebo.[1-3] It is likely that patients who enter a clinical trial for a new drug have found available therapy unsatisfactory. In one study, for example, patients had been titrated to maximum tolerated doses of propranolol, but were still experiencing effort-induced angina.[2] It is therefore likely that the patient population of these studies was relatively refractory to propranolol, and further studies are required before a conclusion can be drawn from these data.

In a single-blind, crossover study of unstable (preinfarction, crescendo) angina, Isoptin (400 mg/day) produced a highly significant reduction in transient ischemic ECG events and nitroglycerin consumption, while propranolol (300 mg/day) did not differ significantly from placebo.[4] In Prinzmetal's variant angina, Isoptin has also proved highly effective.[5]

Please see last page of this advertisement for brief summary of prescribing information.

ISOPTIN® TABLETS (verapamil HCl/Knoll)

Isoptin improves the oxygen balance of the heart in both angina of effort and angina at rest.

Marked therapeutic effects with infrequent serious side effects

In most patients, including those with organic cardiac disease, the negative inotropic action of Isoptin is countered by reduction of afterload, and cardiac index is usually not reduced. Isoptin does not alter total serum calcium levels.

Adverse reaction to Isoptin	Incidence in 1166 patients
Constipation	6.3%
Dizziness	3.6%
Hypotension	2.9%
Headache	1.8%
Peripheral edema	1.7%
Nausea	1.6%
Bradycardia (HR < 50 beats/min)	1.1%
Fatigue	1.1%
CHF or pulmonary edema	0.9%
AV block (third degree)	0.8%

Why Isoptin, and not a beta blocker?

In addition to its high degree of efficacy in both major types of angina, Isoptin requires no special caution in patients with asthma, COPD, diabetes or peripheral vascular disease, including Raynaud's Disease.

Careful patient selection is important

Isoptin is contraindicated in severe left ventricular dysfunction, sick sinus syndrome (except in patients with a functioning artificial ventricular pacemaker), hypotension or cardiogenic shock and second- or third-degree AV block.

Concomitant use with other cardioactive drugs warrants caution

In view of limited experience with concomitant use of Isoptin and beta blockers, Isoptin should be used alone, if possible. If combination therapy is used, it should involve close surveillance of vital signs and clinical status, periodic reassessment of the need for concomitant treatment with the beta blocker, and should probably be avoided in patients with AV conduction abnormalities or depressed left ventricular function. Since concomitant use of calcium antagonists and digoxin increases serum digoxin levels, maintenance digoxin dosage should be reduced and the patient carefully monitored. Until further data are obtained, disopyramide phosphate should not be administered within 48 hours before or 24 hours after Isoptin; and in patients with hypertrophic cardiomyopathy, quinidine should not be administered concomitantly with Isoptin.

Please see next page for brief summary of prescribing information.

ISOPTIN® TABLETS
(verapamil HCl/Knoll)
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C :* There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets. July 1982 2068

CONTENTS

844 Increased R-Wave Amplitude Induced by Acute Myocardial Ischemia in the Dog: A Predictor of Malignant Ventricular Arrhythmias

DANIEL DAVID, ERIC L. MICHELSON, MASAHITO NAITO, MARK SCHAFFENBURG, and LEONARD S. DREIFUS

The ability of an increase in R-wave amplitude to predict the occurrence of malignant ventricular arrhythmia was evaluated in 17 dogs during experimental acute myocardial ischemia. Dogs underwent temporary 15 minute ligation of the left anterior descending artery and, after recovery, ligation of the circumflex coronary artery. During left anterior descending coronary artery ligation, 12 dogs (71%) showed no R-wave increase and no arrhythmia; 5 (29%) developed ventricular arrhythmia, but only 2 of the 5 (40%) had R-wave increases. During circumflex ligation 13 dogs (76%) had both R-wave increases and arrhythmia; 4 (24%) had no arrhythmia, and 3 of the 4 (75%) also had no increase in R-wave amplitude. In dogs with both arrhythmia and R-wave increases, R-wave changes preceded the onset of arrhythmia by a mean of 1 minute 27 seconds. Overall, R-wave increases were highly sensitive (83%), specific (94%), and predictive (94%) for the occurrence of ventricular arrhythmia during acute myocardial ischemia.

849 Ibuprofen-Mediated Infarct Size Reduction: Effects on Regional Myocardial Function in Canine Myocardial Infarction

PHILIP C. KIRLIN, JOSEPH L. ROMSON, BERTRAM PITT, GERALD D. ABRAMS, M. ANTHONY SCHORK, and BENEDICT R. LUCCHESI

Normal, marginal, and ischemic zone regional myocardial contractile function was measured by sonomicrometer crystals in canine myocardial infarction. Regional function was measured in anesthesized dogs after 90 minute left circumflex coronary occlusion and in conscious, unsedated animals 48 and 72 hours after reperfusion through a critical stenosis. Animals received either intravenous ibuprofen or vehicle as a control. Ibruprofen (5.36 mg/kg/h) significantly reduced histochemically determined infarct size at 72 hours but did not improve regional contractile function in normal, marginal, or central ischemic regions at the end of the 90 minute occlusion or after 48 or 72 hours of reperfusion. Inotropic reserve at 72 hours was also unchanged. The assessment of changes in regional myocardial contractile function after infarct size reduction with ibuprofen or other agents may require prolonged observation.

857 Protective Effects on Isolated Hearts With Developing Infarction: Slow Channel Blockade by Diltiazem Versus Beta-Adrenoceptor Antagonism by Metoprolol

CHRISTIAN W. HAMM, FRANCIS T. THANDROYEN, and LIONEL H. OPIE

This study was designed to assess and compare the effects of the beta-receptor antagonist metoprolol with those of the calcium channel inhibitor diltiazem on cellular damage and mechanical function in the isolated working rat heart subjected to coronary artery ligation. The highest concentrations of both agents that could be tolerated in this preparation were compared: diltiazem, 4×10^{-7} *M*; and metoprolol, 10^{-4} *M*. These concentrations were equally effective in reducing enzyme release, which was taken as an index of cellular damage, and preserved high energy phosphate content in the infarcting myocardium. However, the 2 agents exhibited opposite effects on coronary flow rates and mechanical function. Compared with diltiazem, metoprolol reduced total coronary flow, cardiac output, and left ventricular work and efficiency immediately after coronary artery ligation. Diltiazem, however, appeared to have a favorable influence on the mechanical performance of the isolated heart compared with untreated control hearts during the 60 minute duration of regional myocardial ischemia. These benefits were similarly apparent when the hearts were paced to the rate of control hearts. The presumed mechanism was coronary vasodilation, because afterload increased as left ventricular power production increased. These results suggest that further evaluation of diltiazem in other preparations is warranted.

864 Inhibition of Hypoxic Pulmonary Vasoconstriction by Nifedipine

THOMAS KENNEDY and WARREN SUMMER

The effect of nifedipine on the relation between pulmonary arterial pressure and blood flow during normoxia (PAO_2 = 200 mm Hg) and hypoxia (PAO_2 = 50 mm Hg) was evaluated in ventilated pig lungs perfused in situ with the animal's own blood. Nifedipine, given as a 0.1 or 10 μg/kg bolus into the pulmonary artery, caused a dose-dependent reduction of pulmonary vasoconstriction caused by hypoxia. We conclude that nifedipine is a potent pulmonary vasodilator which markedly attenuates hypoxic pulmonary vasoconstriction.

Continued on Page A59

Your Persantine patients deserve this 3-minute checkup

(to be sure they're getting full benefits)

1. **Has the patient been taking Persantine long enough?** It often takes two to three months for clinical improvement to manifest itself.
2. **Is the patient on an optimum dosage regimen?** With 25 mg, 50 mg, and 75 mg tablets, it's easy to establish a convenient, economical regimen for each patient.
3. **Is the patient getting enough Persantine?** Most patients need 150 mg daily in divided doses...some require even more.
4. **Does the patient take Persantine regularly?** Encourage patients to take it daily, without a break.
5. **Is the patient getting genuine Persantine?** Ask to see the tablets... and be sure to write "Dispense as written" or "No substitution" on your Persantine prescriptions.

(dipyridamole)

Tablets of 25, 50 and 75 mg

Persantine®

The experienced dipyridamole

INDICATIONS—Based on a review of this drug by the National Academy of Sciences-National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25, 50 and 75 mg

For complete details, please see the full prescribing information.

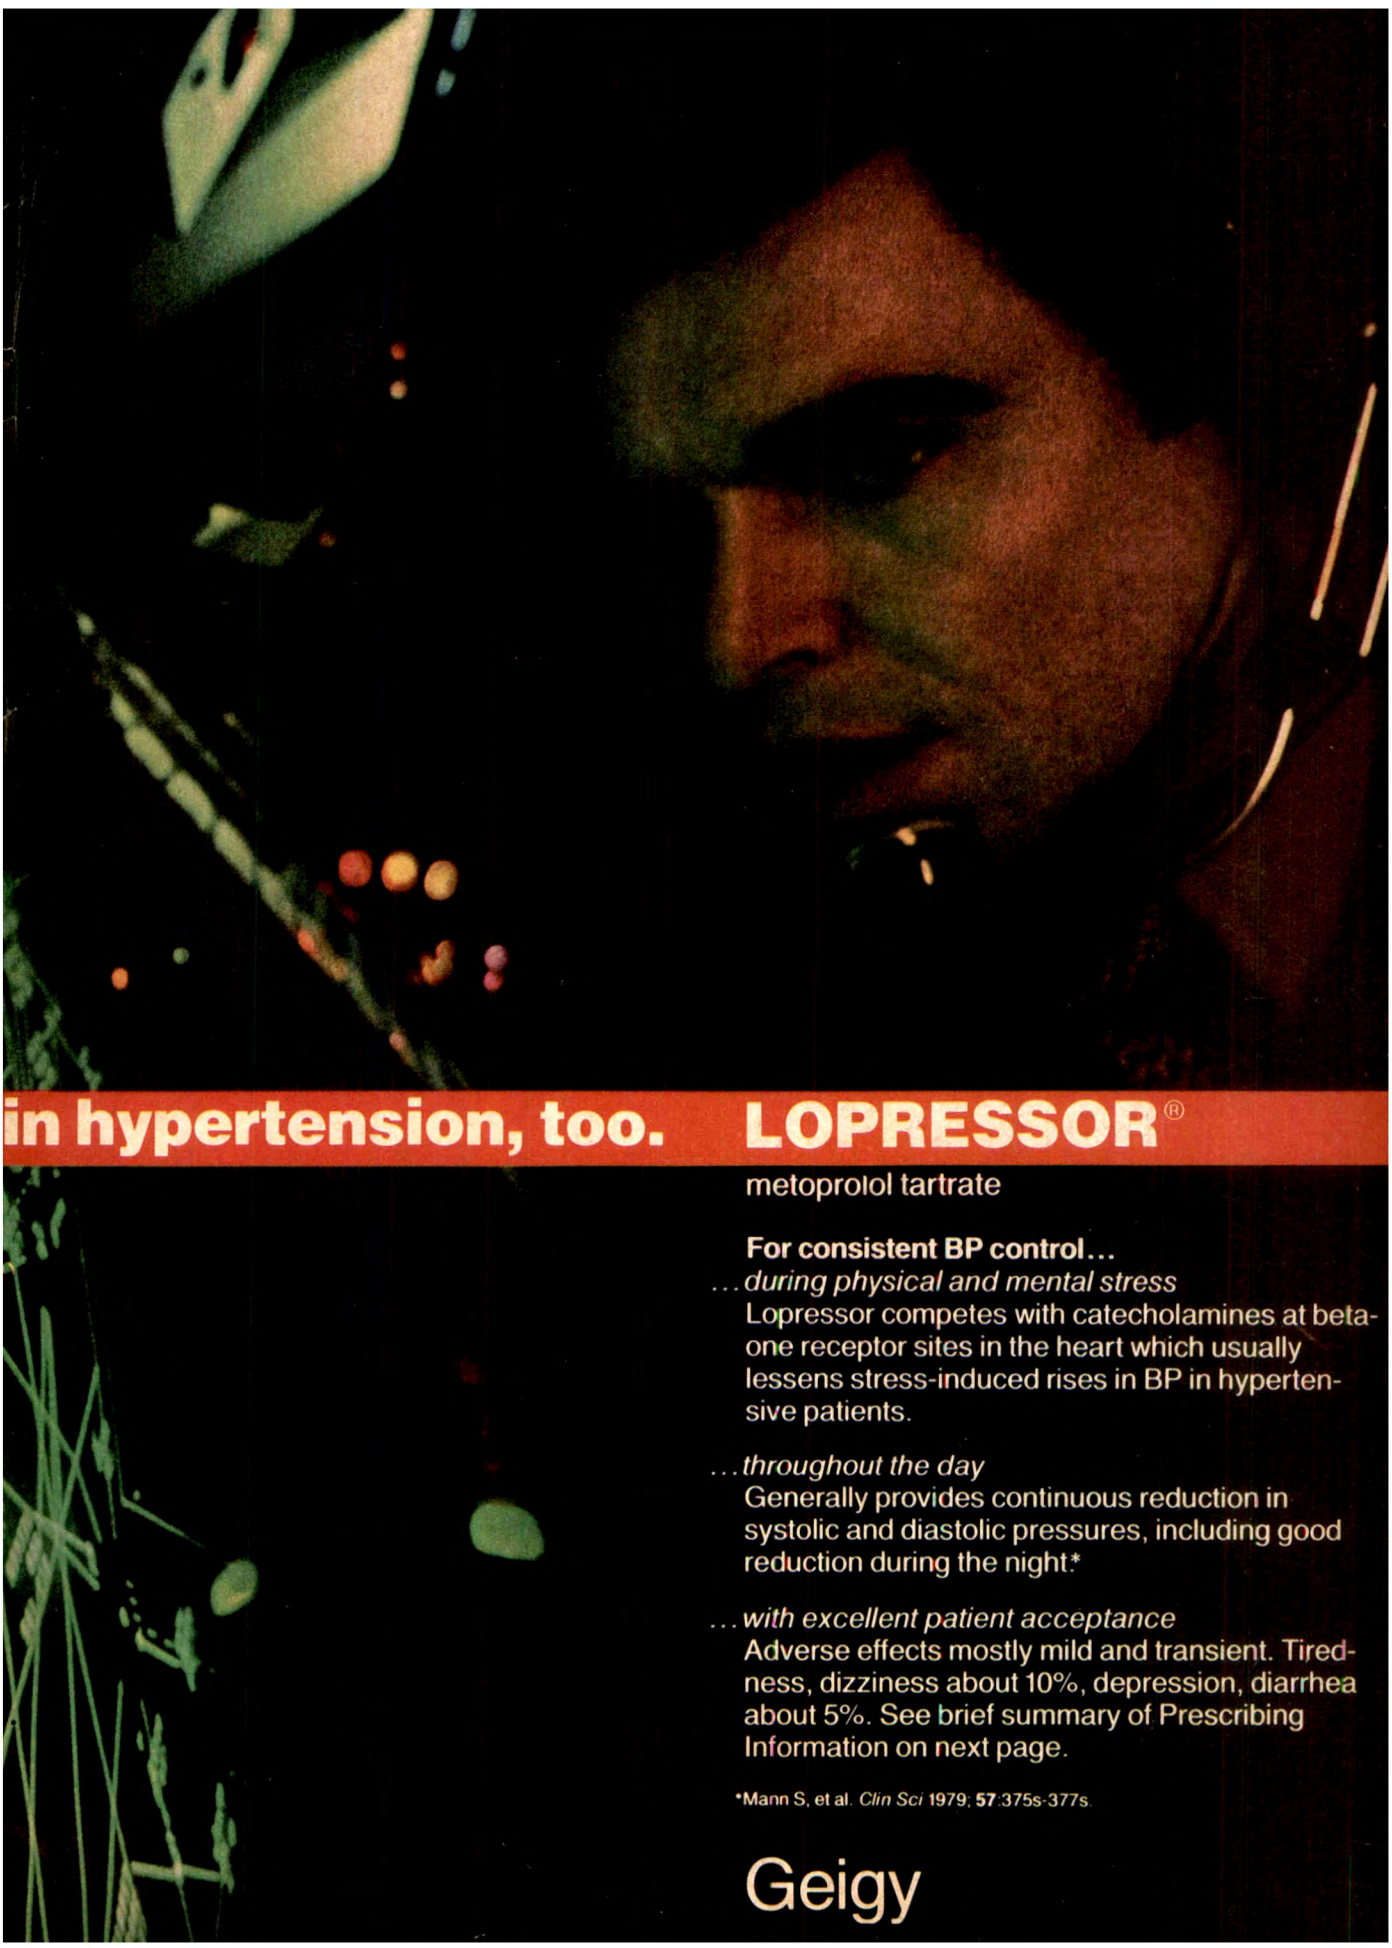
Consistent control counts..



in hypertension, too. LOPRESSOR®

metoprolol tartrate

For consistent BP control...

...during physical and mental stress
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

...throughout the day
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

...with excellent patient acceptance
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

metoprolol tartrate

An antihypertensive beta-blocking agent — Tablets of 50 mg; Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.
Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).
Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.
In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.
Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.
Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**
Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.
Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.
Impaired Hepatic or Renal Function: The drug should be used with caution in patients with impaired hepatic or renal function.
Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.
Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.
Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.
Usage in Children: Safety and effectiveness in children have not been established.
Adverse Reactions Most adverse effects have been mild and transient.
Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.
Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**
Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**
Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.
Allergic: Pruritus has occurred in less than 1 of 100 patients.
Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.
Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.
Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.
Cardiovascular: Intensification of AV block (see **Contraindications**).
Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.
Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.
Miscellaneous: Reversible alopecia.
Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.
Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.
This drug should be stored at controlled room temperature and protected from moisture.
How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.
Store at controlled room temperature and protect from moisture.
Dispense in tight, light-resistant container (USP).

869 Effects of Angiographic Contrast Medium on Isolated Canine Coronary Arteries

HECTOR LARDANI, GUSTAVO RINALDI, and HORACIO CINGOLANI

A widely used angiographic dye elicited marked relaxation in isolated canine coronary arteries previously contracted by either high potassium or norepinephrine. This dose-dependent effect was not prevented either by beta blockade or by an increase in osmolarity similar to the one produced by the dye. This relaxant action and the one elicited by nitroglycerin were additive. Changes in cyclic guanosine or adenosine monophosphate could not account for the relaxant effect of the contrast medium.

874 Digital Intravenous Ventriculography: Analysis and Validation of Wall Thickness Changes During Ischemia and Inotropic Stimulation in Dogs

ROBERT A. SLUTSKY, KENNETH H. GERBER, and CHARLES B. HIGGINS,
with the technical assistance of FRANK H. HAIGLER and FRED G. WERNER

Regional ventricular wall thickness was assessed in anesthesized dogs using digital intravenous ventriculography in a control state, after subtotal and total coronary occlusion, and after the administration of isoproterenol. These measures of wall thickness correlated well with simultaneous measurements made by sonomicrometers placed in the base and distal wall of the ventricle. Thickening was found asymmetric, being greater as the distal wall and apex were approached. These relations were maintained during ischemia and inotropic stimulation. We conclude that digital intravenous ventriculography can be used to assess changes in wall thickness with a high degree of accuracy in dogs.

SYMPOSIUM ON VERAPAMIL THERAPY FOR ANGINA PECTORIS

MILTON PACKER, Guest Editor, and WILLIAM H. FRISHMAN, Guest Co-Editor

881 Verapamil Therapy for Stable and Unstable Angina Pectoris: Calcium Channel Antagonists in Perspective

MILTON PACKER and WILLIAM H. FRISHMAN

This symposium reviews the evidence concerning the therapeutic application of verapamil in patients with angina pectoris. Because of the increasing number of calcium antagonists being developed for clinical use, physicians are faced with the question of which drug to choose. Since available agents appear to be of comparable efficacy, it is likely that the choice of a drug in an individual patient will be determined more by which drug is better tolerated than by which agent is more effective. Verapamil appears to cause adverse reactions less frequently than does nifedipine, but nifedipine is often preferred because it is thought to possess less potential to depress cardiac function and interact with beta-blockers. However, both agents may interact with beta-blockers and both may depress cardiac performance in patients with compromised ventricular function; no comparative studies in the same patients have been performed. Since beta-blockers have an established role in the prophylaxis of future cardiac events in patients with recent myocardial infarction, the critical question concerning the choice of a calcium antagonist remains the relative safety and effectiveness of verapamil versus nifedipine in patients already treated with beta-blocking agents. The answer to this question awaits the results of future clinical trials.

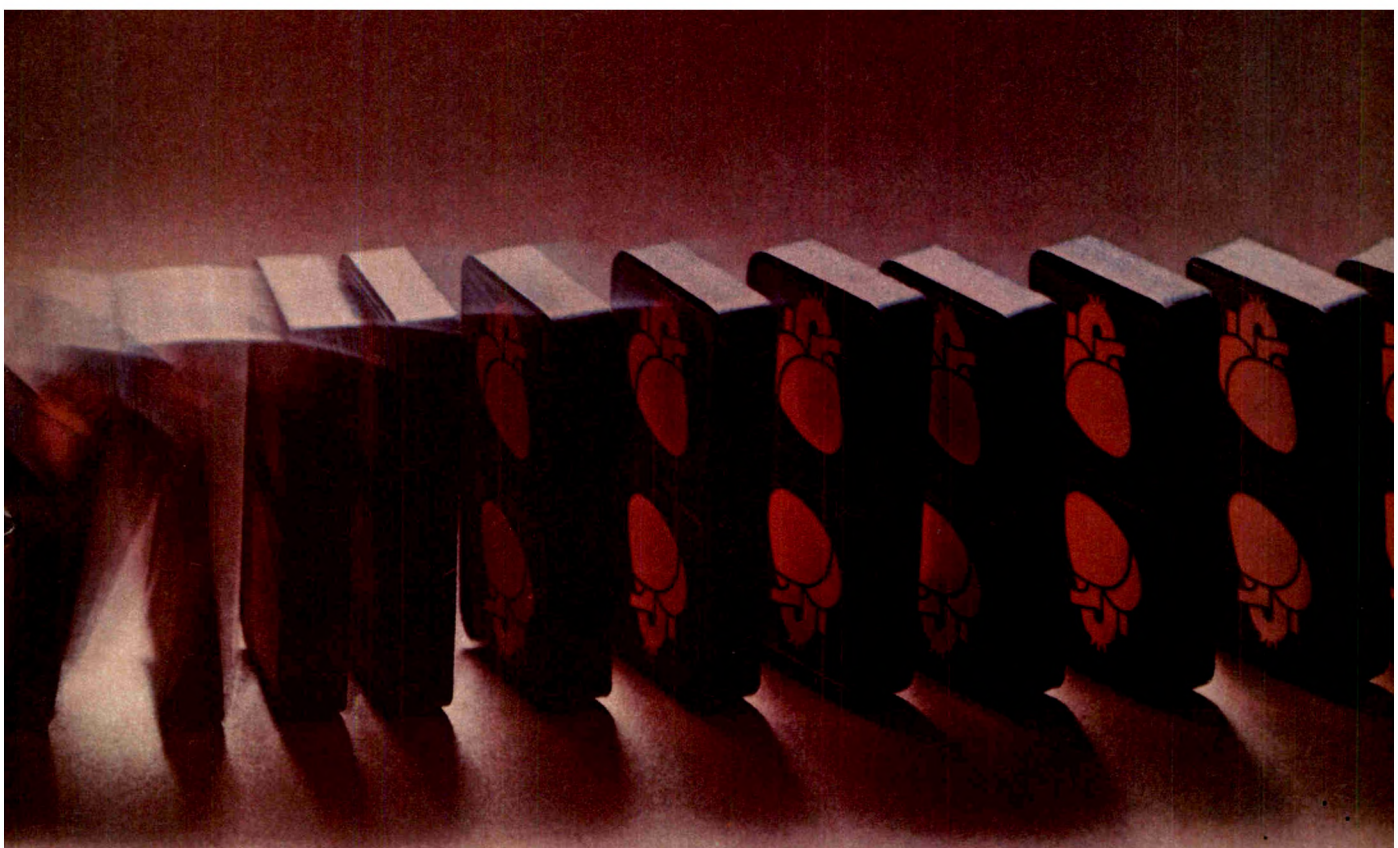
BECAUSE ONE THING CAN LEAD



TO ANOTHER INDERAL®
(PROPRANOLOL HCl)

A MAJOR NEW INDICATION...

COMING SOON.

Please see next page for Brief Summary of Prescribing Information.

INDERAL®
(PROPRANOLOL HCl)

For Hypertension • Angina • Arrhythmias • Migraine

A MAJOR NEW INDICATION... COMING SOON.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia, congestive heart failure, intensification of AV block, hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness, mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

--Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

--Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

--Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

--Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

--Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

PART I: PHARMACOLOGIC AND HEMODYNAMIC ACTIONS AND INTERACTIONS

886 Pharmacologic and Hemodynamic Mechanisms Underlying the Antianginal Actions of Verapamil

BRAMAH N. SINGH, CHRISTOPHER Y. C. CHEW, MARTIN A. JOSEPHSON, and MILTON PACKER

In patients with a severely reduced ventricular ejection fraction and high ventricular filling pressure, verapamil may produce clinical and hemodynamic deterioration. Computer-assisted angiographic analysis has shown that verapamil dilates normal as well as narrowed epicardial coronary vessels and reverses ergonovine- and sympathetically provoked coronary vasoconstriction. Intravenous verapamil administration reduces coronary arterial resistance and enhances coronary sinus flow with variable effects on myocardial oxygen consumption. The drug prevents the ischemic consequences of angina produced by atrial pacing; after verapamil administration, pacing-induced lactate production is lessened, and ischemia-related decreases in left ventricular ejection fraction are prevented. During chronic therapy, the effects of verapamil on regional and global ventricular function are similar to those of propranolol during supine bicycle exercise. However, verapamil has a significantly smaller effect on the rate-pressure product at rest and during exercise; this suggests that its antianginal mechanism of action, unlike that of beta-blockers, may not be related solely to a reduction in oxygen demand. These data indicate that the mechanisms underlying the antianginal effects of verapamil are complex and are likely to be multifactorial.

894 Verapamil and Digoxin: Their Respective Effects on Atrial Fibrillation and Their Interaction

HERMAN O. KLEIN and ELIESER KAPLINSKY

Although digitalis has long been used in the management of patients with atrial fibrillation, it does not block the excessive increase in ventricular rate which occurs in such patients during mild exercise; in contrast, this inappropriate response is effectively blocked by verapamil. During regular sinus rhythm, atrioventricular (AV) node works well as a *delaying* structure (the P-R interval), and the ventricular rate is a function of the sinus rate only. However, in atrial fibrillation, the AV node has to adopt the role of a *filter* for numerous wave fronts of activity, a function it fulfills poorly, especially during the enhanced sympathetic responses and decreased vagal tone that accompany exercise. In patients with atrial fibrillation, during exercise these autonomic alterations override the vagal effects of digitalis on the AV node, but verapamil remains effective by virtue of its direct action on the slow channel ionic fluxes within the AV nodal cells. The beneficial effect of verapamil on ventricular rate is accompanied by a significant improvement in maximal exercise capacity in patients with atrial fibrillation receiving long-term oral verapamil therapy; thus, it appears superior to digoxin in the treatment of chronic atrial fibrillation.

903 Hemodynamic and Clinical Effects of Combined Verapamil and Propranolol Therapy in Angina Pectoris

MILTON PACKER, MARTIN B. LEON, ROBERT O. BONOW, JOSHUA KIEVAL, DOUGLAS R. ROSING, and V. BALA SUBRAMANIAN

Because of their common negative chronotropic and inotropic effects combined therapy with beta-adrenergic blocking drugs and calcium channel antagonists has long been feared to produce synergistic cardiodepressant effects. To evaluate whether such fears are justified when such therapy is used in patients with angina pectoris, 5 hemodynamic and clinical studies were conducted. These studies indicate that in patients with preserved ventricular function treated with low or moderate doses of propranolol, verapamil produces little change in cardiac performance; this was not significantly different from the effects seen with verapamil in the absence of beta blockade. In patients receiving high doses of propranolol, verapamil produced modest but significant cardiodepressant effects; these could be avoided by withdrawal of propranolol for 24 hours. Adverse reactions when they occurred appeared primarily hemodynamic rather than electrophysiologic in nature. Short-term (48 hours) and long-term (4 weeks) randomized controlled trials demonstrated that combined therapy with verapamil and propranolol was superior not only to placebo but also to the responses observed with either drug used alone.

Important Information

Indications
The Cordis Model 233D Sequicor θ (Theta) pacer is a two-channel pacer intended for permanent, two-chamber cardiac pacing.

Adverse Effects
The following list includes a number of complications related to pacer therapy that have been reported in the medical literature. Noninvasive techniques for assessing and managing such complications are available to the physician. Malfunctions occur randomly and may occur at any time after implantation.

Complications Associated with Pacer Therapy
Pacer – battery depletion, component malfunction, electromagnetic interference, decreased sensitivity
Lead – unsatisfactory electrode position, fracture displacement, penetration/perforation of heart wall, faulty connection with pacer
Body – reaction, infection/erosion, increase in stimulation threshold

Contraindications
Atrial-synchronized ventricular pacing and DDD sequential pacing modes are contraindicated for use in the presence of chronic atrial flutter or atrial fibrillation. If these conditions are demonstrated, atrial sensitivity can be programmed "off" to a nonatrial sensing mode such as VVI.

Caution: Investigational device. Limited by Federal (U.S.A.) law to investigational use.

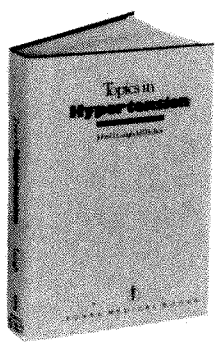
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

CONTENTS

PART II: STUDIES IN ANGINA AT REST

913 **Verapamil Therapy for Prinzmetal's Variant Angina: Comparison With Placebo and Nifedipine**

MICHAEL D. WINNIFORD, STACEY M. JOHNSON, DAVID R. MAURITSON, JAMES S. RELLAS, GREGORY A. REDISH, JAMES T. WILLERSON, and L. DAVID HILLIS

This study was performed to assess the efficacy and safety of verapamil in patients with variant angina and to compare verapamil and nifedipine in such patients. In 27 patients, placebo and verapamil were administered in a long-term, randomized, double-blind study of 9 months' duration. In comparison with placebo, verapamil reduced the frequency of angina, nitroglycerin use, transient episodes of electrocardiographic S-T segment deviation (as assessed by 2-channel Holter monitoring), and hospitalizations required for clinical instability. Subsequently, 23 of the patients were treated with nifedipine in a nonblinded fashion for 2 months, and this agent exerted a beneficial effect similar to that of verapamil. Finally, gated equilibrium blood pool scintigraphy, performed in 10 patients at rest and during exercise during treatment with placebo, verapamil, and nifedipine, demonstrated that neither calcium antagonist caused a deterioration of left ventricular performance. It is concluded that long-term oral verapamil and nifedipine are each superior to placebo and are of similar efficacy in patients with variant angina, and tha neither agent adversely influences left ventricular performance in patients with relatively normal left ventricular function.

919 **Verapamil Therapy for Unstable Angina Pectoris: Review of Double-Blind Placebo-Controlled Randomized Clinical Trials**

JAWAHAR MEHTA and C. RICHARD CONTI

The effectiveness of verapamil in the management of patients with unstable angina pectoris associated with obstructive coronary artery disease was evaluated in 2 double-blind placebo-controlled randomized clinical trials. In the first study, verapamil was compared with placebo using alternating 48 hour treatment periods in a multiple crossover protocol. Verapamil was superior to placebo in abolishing symptomatic and asymptomatic ischemic episodes; there were 127 ischemic events during treatment with placebo but only 27 episodes during therapy with verapamil ($p < 0.006$). In the second study, verapamil and placebo were compared using a double-blind randomized parallel design, in which the choice of drug was altered and the doses administered were increased according to the individual responses. Verapamil reduced anginal attacks in 12 of 13 patients, but placebo was effective in only 1 of 6 ($p < 0.025$); verapamil reduced daily anginal attacks from 3.2 to 0.6/day ($p < 0.01$). These studies show that verapamil is highly effective in the short-term management of patients with unstable angina secondary to coronary artery disease.

923 **Verapamil Versus Propranolol for Angina at Rest**

OBERDAN PARODI, IGNAZIO SIMONETTI, ANTONIO L'ABBATE, and ATTILIO MASERI

The results of 3 clinical trials comparing the effectiveness of verapamil and propranolol in patients with angina at rest are reviewed. In 17 patients enrolled in a randomized triple-crossover study, verapamil was superior to propranolol in preventing ergonovine-induced coronary artery spasm ($p < 0.001$). In 18 patients with angina at rest evaluated in a double-blind crossover study, both verapamil and propranolol reduced the number of episodes of angina at rest (from 3.0 to 1.7/day with propranolol [$p < 0.05$] and to 0.2/day with verapamil [$p < 0.001$]); the degree of improvement with verapamil was superior to that seen with propranolol ($p < 0.005$). In 10 patients with angina at rest evaluated in a single-blind multiple crossover trial which assessed symptomatic and asymptomatic ischemia, the number of ischemic events was reduced significantly by verapamil (5 ± 1 episodes/48 hours) but not by placebo or propranolol (25 ± 3 and 23 ± 3 episodes/48 hours, respectively). These studies confirm the effectiveness of verapamil in the management of patients with angina at rest; in contrast, the effectiveness of propranolol in this syndrome appears comparable to that of placebo.

COMP-SCAN
HOLTER ANALYSIS...
RESULTS THAT SPEAK FOR THEMSELVES
compu-scan
GUTMAN
Medical Systems

accurately locate and classify each irregular heartbeat that occurs in a 24 hour Holter ECG procedure. Comp-scan then compiles and presents that information in a format that enables rapid verification and interpretation of scanned results...so, the cardiologist can concentrate on patient diagnosis and treatment.

Comp-scan's rapidly available and precise reports are presented in the format needed by the technician and the cardiologist. Comprehensive summaries list all major events with ectopics classified by type and by the hour of occurrence. Classified events can be quickly and easily verified using the minute by minute breakdown of any selected hour. Or, the user can verify results by specific arrhythmia type using Comp-scan's exclusive automated arrhythmia search feature. Summary reports are presented on the color screen for immediate review, with permanent records provided by the high speed printer. ECG complexes are presented on a separate large display screen with permanent printout available from the 2-channel chart recorder.

ACCURATE RESULTS

Comp-scan's computer has been programmed to recognize ectopic events. Once the operator has defined a patient's normal ECG, Comp-scan works by itself to locate and classify each ectopic event. Advanced hardware and software design allows Comp-scan to reject artifact while accommodating normal physiological changes.

Comp-scan's computer never gets tired or looks away. Every heartbeat of every Holter tape is analyzed with precisely the same criteria. While the system is automatically scanning, the operator can perform other tasks. And when analysis is complete, the operator's expertise is focused on verification and interpretation of results.

VERIFIABLE RESULTS

Comp-scan can recall every heartbeat by the minute in which it occurred. So, each ectopic event that was detected by Comp-scan can be quickly displayed on the ECG screen for rapid verification. And those results can be edited and documented with patient ID for permanent record.

CLINICAL STUDIES

Medical Versus Surgical Treatment of Unstable Angina

HERBERT N. HULTGREN, MD, UDIPI R. SHETTIGAR, MD, and D. CRAIG MILLER, MD

A prospective, nonrandomized data bank study of the effect of medical versus surgical management of patients with unstable angina included all patients with unstable angina seen at 1 hospital over an 8 year period. Patients were entered into the study after an initial 5 day period of medical treatment. Entry characteristics were similar in 104 surgical patients and 124 medical patients. The mean follow-up period was 52 months. The operative mortality rate was 2% (2 of 104). The incidence of operative infarction was 13% (13 of 104). Twenty-seven medical patients (22%) had late surgery for progressive angina without operative mortality. Seven year survival (Mantel-Haenszel) was 65% for the medical group and 85% for the surgical group when analyzed by initial treatment ($p = 0.012$). Analysis by the crossover method where crossover medical patients are followed up only to the date of surgery yielded similar results ($p = 0.008$). Nonsurvivors were compared with survivors and had a higher incidence of the following entry characteristics: (1) age greater than 60 years; (2) diastolic blood pressure greater than 89 mm Hg; (3) ST-T changes in the resting electrocardiogram; (4) 3 vessel disease; (5) elevated left ventricular diastolic pressure (at rest); and (6) elevated left ventricular diastolic pressure (exercise). None had single vessel disease. The incidence of infarction (fatal and nonfatal) in 5 years was 17% in the medical group and 22% in the surgical group. In the latter group 13% had a perioperative infarct and 9% had a late infarct. Symptom relief was greater in the surgical group. At 5 years 62% had no angina and only 8% had severe angina compared with 37% and 24%, respectively, in the medical group. Thus surgical management of selected patients with unstable angina appears preferable to medical therapy in view of improved survival and greater symptom relief. Whereas the total incidence of infarction was not reduced this was, in part, related to a 13% incidence of perioperative infarction. Improved methods of myocardial protection have since reduced this incidence to 3.0% in our hospital.

Several prospective randomized studies of medical versus surgical management of unstable angina have resulted in the following general conclusions after a 2 to 3 year follow-up period[1-4]: (1) A preliminary period of intensive medical management of 4 to 5 days before surgical treatment is not hazardous and appears to result in a lower operative mortality and morbidity. (2) Surgical treatment provides superior symptomatic relief compared with medical treatment. (3) The incidence of failures in medical treatment over a 3 year follow-up period is appreciable (20 to 39%). Such patients usually exhibit excellent relief of symptoms after coronary bypass surgery. (4) The incidence of perioperative infarction is sufficiently high so that the incidence of infarction is similar in both treatment groups after a follow-up period of 2 to 3 years. (5) Patients without left main coronary artery disease do not exhibit improved survival with surgical therapy compared with those in medical treatment alone. Large scale randomized studies with a longer follow-up period will provide more

From the Cardiology and Cardiovascular Surgery Services, Veterans Administration Medical Center, Palo Alto, California. This study was supported in part by research funds from the Veterans Administration, Palo Alto California. Manuscript received July 6, 1981; revised manuscript received May 3, 1982, accepted May 6, 1982.

Address for reprints: Herbert N. Hultgren, MD, Cardiology Service, Veterans Administration Medical Center, 3801 Miranda Avenue, Palo Alto, California 94304.

secure data regarding the effect of treatment methods on survival and the incidence of nonfatal infarction.

A prospective, randomized study is statistically the most sound approach to the evaluation of 2 modes of therapy. Such studies usually ensure that the 2 treatment groups are identical, and bias in the assignment of patients to treatment groups is avoided. However, the randomized study still presents several problems in the application of data to clinical practice. The patients selected for entry into a randomized study may not be representative of all the patients with the disease entity being studied. Physicians may be unwilling to enter a patient into a study for reasons of personal bias. Physicians may, for example, prefer to treat patients with mild symptoms medically, but in the presence of severe or persisting symptoms surgical treatment may be selected. Patients may be unwilling to enter a study in which their treatment is determined by chance. In published randomized studies of unstable angina it is not known how many eligible patients were not entered.

This problem is avoided in prospective data bank studies in which all eligible patients are entered into the study. If the selection of therapy is largely a random process the 2 treatment groups may have similar entry descriptors and thus a statistically valid comparison of outcome can be attained. If this is not the case patients in predetermined subgroups can be matched regarding important entry descriptors that determine survival.

A preliminary report of the results of therapy in unstable angina in a consecutive series of patients seen at this hospital from 1970 to 1975 has been published.[5] The entry descriptors of the 2 treatment groups were similar. Because the study included all eligible patients seen at 1 hospital and surgery was performed by a single, experienced operating team with a low operative mortality, this study was continued for an additional 2 years. We report herein the results of this investigation up to August 1, 1980.

Methods

Definition of unstable angina: All patients fulfilled at least 1 of the following clinical criteria of unstable angina: (1) stable angina with an increase in severity or frequency of symptoms over the preceding 2 months; (2) recent onset angina with increasing severity or frequency of symptoms over the preceding 2 months (rest angina was not a requirement of these 2 groups); (3) acute coronary insufficiency with at least 1 episode lasting more than 15 minutes within the preceding 2 weeks. Acute coronary insufficiency was defined as prolonged (more than 15 minutes) anginal pain occurring at rest and not promptly relieved by nitrates. Patients with acute myocardial infarction within 3 months of hospital entry were excluded. An additional entry criterion was the presence of transient ST-T wave changes compatible with ischemia. If such changes were not present a positive electrocardiographic exercise test was required.

Acute myocardial infarction excluded patients from the study. The appearance of new Q waves or persistent T-wave inversion associated with significant enzyme elevation was considered evidence of acute infarction.

Daily serum enzyme levels were determined in all patients during the initial hospital study. If 2 successive levels of serum creatine kinase, glutamic oxaloacetic transaminase and lactic dehydrogenase were elevated more than twice the upper limit of normal, the patient was excluded from the study. MB fractions of serum creatine kinase were not obtained in patients who were in the earlier years of the study.

TABLE I Clinical Presentation in 228 Patients With Unstable Angina

	Medical Group (n = 124)	Surgical Group (n = 104)
Stable angina, increased severity (%)	51	72
Angina of recent onset (%)	23	22
Acute coronary insufficiency (%)		
With other symptoms	71	67
Alone	19	12
Mean duration of acute symptoms (days)	17	25
Chest pain >48 h in hospital (%)	34	35

Hospital observation period: A 5 day hospital observation period was a requirement of the study. Patients who died, who had an acute myocardial infarction, or who had complications that would be a contraindication to surgical treatment during the observation period were excluded from the study.

Study group: All patients who were admitted to the hospital from January 1970 to July 1977 who fulfilled the above entry criteria were included in the study. Patients who had any condition that would be a contraindication to coronary bypass surgery were excluded. A total of 124 patients at entry received medical management and 104 patients had surgical treatment.

Coronary arteriography: All patients who had surgical treatment had coronary arteriography and left ventricular angiography. Not all medical patients had arteriography, especially in the earlier years of the study because at that time the risk of arteriography was greater, the importance of left main coronary disease was not appreciated, and arteriography was not considered essential for the initiation of medical treatment. A total of 184 patients had coronary arteriography. This included 104 surgical patients (100%) and 80 medical patients (65%).

Treadmill tests: The Bruce protocol was used in these tests. A test was considered positive when an S-T depression of 0.1 mV or more with a duration of 0.08 or more occurred during or immediately after a symptom-limited test. Treadmill tests were performed in 56 surgical patients (54%) before operation and in 81 medical patients (66%).

Chest roentgenograms were not systematically evaluated in the previous study. In this study chest films were retrieved on all available patients and the cardiothoracic ratio and cardiac volume were calculated by a single observer using standard methods.[6]

Other details of the methods have been summarized in a previous report.[5]

End-points: The following data end-points were used in the evaluation of therapy: (1) *Death* after 5 days of hospital admission or during the follow-up period. (2) *Acute myocardial infarction* after 5 days of hospital admission: Acute infarction was diagnosed when new significant Q waves appeared with evolutionary changes in the presence of a compatible clinical presentation. Perioperative infarction was diagnosed using the same criteria. (3) *Hospital readmission for cardiac reasons:* These reasons included recurrent episodes of angina, acute coronary insufficiency, suspected or proved myocardial infarction, congestive heart failure, cardiac arrhythmia, or postoperative complications. (4) *Relief of*

TABLE II Risk Factors at Entry in 228 Patients With Unstable Angina

	Medical Group (n = 124)	Surgical Group (n = 104)
Age (yr)	58	55
Positive family history (%)	44	40
History of diabetes (%)	13	19

≥250	34	38

BP = blood pressure.

angina: Angina was evaluated as absent, moderate or severe on the basis of the average level of symptoms over 1 month before the follow-up interview. Angina was described as absent when no chest pain had been noted for the preceding month. Moderate angina consisted of episodes that occurred at least weekly but not daily, were easily relieved by nitrates, and did not interfere with normal activity. Anginal episodes that occurred daily and limited normal activity were classified as severe. (5) *Medical treatment failures:* Patients in the medical management group who had subsequent aortocoronary bypass surgery for persisting symptoms despite adequate medical treatment were classified as medical treatment failures (medical crossovers).

Data analysis: Data on each patient were entered in a card file system and analyzed using the Statistical Package for the Social Sciences (SPSS) routine at the Stanford Computation Center. Student's unpaired t tests were used to compare entry data for the patients in the group with unstable angina. Paired t tests were used to assess the statistical significance of changes in variables over the follow-up period in both groups. P values greater than 0.05 were not considered significant. Survival curves were constructed in a standard manner. Comparisons between the 2 treatment groups were made up to 7 years of follow-up by the Mantel-Haenszel test. Survival was evaluated in the following manner: (1) initial treatment assigned; (2) crossover method. Medical patients who had late surgery (Med-ops) were counted as lost to follow-up at the time of surgery. Total deaths and cardiac deaths were analyzed separately.

Exclusions: A total of 238 patients met the initial diagnostic criteria for unstable angina after 48 hours of hospitalization. Ten of these patients were excluded from the study.

TABLE III Electrocardiographic Data in 228 Patients With Unstable Angina

	Medical Group	Surgical Group
Acute changes (%)		
T-wave inversion	60	55
S-T depression	41	43
S-T elevation	21	22
Stable infarct pattern (%)	50	41

TABLE IV Treadmill Test Results in Patients With Unstable Angina

	Medical Group	Surgical Group
Patient (n)	81	56
Positive tests (%)	72	77
Mean duration of exercise (s)	344	346
Mean maximal heart rate (beats/min)	128	133
Mean double product (systolic BP × heart rate ÷ 100)	204	208

Five had an acute nonfatal infarction before the 6th hospital day. Two patients had insufficient coronary disease and 2 had inoperable coronary disease. One patient died on the 3rd hospital day from acute infarction.

Results

Comparability of treatment groups: *Clinical presentation:* The clinical features of unstable angina in the 2 treatment groups are summarized in Table I. These features are similar in the 2 groups except for a larger number of surgical patients who had stable angina with increasing symptoms (72 versus 51%). This difference is not statistically significant.

Risk factors in the 2 groups at entry are summarized in Table II. There are no significant differences.

Electrocardiographic data: The data from the resting electrocardiograms are similar in the 2 groups (Table III). In the medical group slightly more patients had electrocardiographic evidence of prior infarction. This difference is not significant.

Treadmill tests (Table IV): No differences are present.

Chest roentgenograms: The cardiothoracic ratios and the cardiac volumes of the 2 treatment groups are summarized in Table V. There was no significant difference in the prevalence of cardiothoracic ratios greater than 50%.

Increase in serum enzyme level: It is well recognized that many patients with unstable angina may have a modest, transient increase in serum enzyme level. Table VI indicates the mean value of the single highest serum enzyme determination observed during the first 48 hours of hospitalization in the 2 treatment groups. No significant differences are evident.

Hemodynamic features: The arteriovenous oxygen differences and left ventricular end-diastolic pressures are summarized in Table VII. The surgical group had slightly higher left ventricular end-diastolic pressure

TABLE V Chest Roentgenographic Data in Patients With Unstable Angina

	Medical Group	Surgical Group
Patients (n)	69	55
Mean cardiothoracic ratio (%)	44.2	44.6
Cardiothoracic ratio ≥50% (%)	23	25
Mean estimated cardiac volume (ml)	511	510

TABLE VI Highest Serum Enzyme Values* During Hospital Observation Period in 216 Patients With Unstable Angina

	Medical Group	Surgical Group
Patients (n)	118	98
Mean creatine kinase (range)	89 (1–537)	53 (3–481)
Creatine kinase >2 times upper limit of normal (%)	17	9
Mean serum glutamic oxaloacetic transaminase (range)	38 (9–144)	31 (2–151)
Mean lactic dehydrogenase (range)	225 (10–950)	222 (79–1100)

* The upper limits of normal in our hospital are as follows: creatine kinase 75, serum glutamic oxaloacetic transaminase 40, and lactate dehydrogenase 300 units.

both before and after contrast medium injection. These differences are not significant.

Angiographic data (Table VIII): The incidence of left main coronary disease was greater in the surgical group (12.5%) than in the medical group (7.1%). This difference is not significant. The surgical group had a lower incidence of 1 and 2 vessel disease and a higher incidence of 3 vessel disease. These differences are not significant.

Surgical treatment: Aortocoronary bypass surgery was performed in 104 patients initially selected for surgical management. The 30 day operative mortality rate was 2%. Perioperative infarcts occurred in 13 patients (13%). All of these patients had new, persisting Q waves plus diagnostic serum enzyme elevations. Surgery was performed at a later date in 27 medical patients with no operative deaths and 4 perioperative infarctions (14%).

The results of surgery in the initial surgical group of 104 patients are summarized in Table IX. Late shunt angiograms were performed in 37 patients (35%) a mean of 12 months after surgery. Twenty-four patients (66%) had all grafts open and 3 (8%) had all grafts closed. Ninety-two % of patients had at least 1 patent graft.

Follow-up results (Table X): Follow-up data to September 1, 1979 are available on 96 medical patients

TABLE VII Hemodynamic Features of Patients With Unstable Angina

(77.4%) and 94 surgical patients (90%). The mean follow-up duration is 52 months, and all patients have been followed up for at least 14 months. Fifty-eight patients have been followed up for 5 years.

In the medical group the overall mortality rate was 18.5%, compared with 10% in the surgical group. The incidence of cardiac deaths in the medical group was 15% compared with 10% in the surgical group. These differences are statistically significant ($p < 0.005$). When patients with left main coronary disease were removed from each group the difference was essentially unchanged. A 2-way analysis of survival at 7 years demonstrated improved survival in the surgical group. The analysis included (1) treatment initially chosen; medical crossovers are counted as patients treated medically; and (2) the crossover method; medical crossovers are counted as lost to follow-up at the time of operation.

In each of the analyses there was a significantly greater improvement in survival in the surgical patients than in the medically treated patients. The results are the same for total mortality and cardiac mortality as end-points (Table XI, Fig. 1 and 2.)

The total incidence of myocardial infarction (fatal and nonfatal) was 17% in the medical group and 22% in the surgical group. The infarcts in the surgical group

TABLE XII Symptoms in Unstable Angina: Comparison of Medical Versus Surgical Treatment*

	Medical Group	Surgical Group
Number	85	118
No angina (%)	27	63
Moderate angina (%)	46	27
Severe angina (%)	27	10
Mean propranolol dose (mg)†	170	112
Used nitroglycerin >10 times a week	19	15

* All surgical patients versus patients who remained on medical treatment.
† Mean value for those patients taking propranolol.

included the 13% incidence of nonfatal perioperative infarcts (Table X, Fig. 3).

The degree of relief of angina was substantially greater in the surgical group. Sixty-three % of the surgical patients had no angina at 39 months compared with 27% of the medical group. Only 10% of the surgical group had severe angina compared with 27% of the medical group.

Further data indicating more substantial relief of angina in the surgical group are shown in Table XII. Sixty-three % of surgical patients were taking no medication for angina and the mean propranolol dose for surgical patients taking propranolol was 112 mg/day. In contrast, only 28% of the medical group was not taking propranolol and the mean propranolol dose for medical patients was 170 mg/day.

The incidence of late hospital entries for cardiac symptoms was similar in both groups. Forty percent of the surgical group had at least 1 late hospital entry, compared to 32% of the medical patients. Hospital entries purely for elective follow-up studies or noncardiac reasons were excluded.

Late surgery in medically treated patients: Twenty-seven patients (22%) who initially received medical treatment had late surgery at a mean interval of 15 months (Fig. 4). No operative deaths occurred in this group, and 1 late cardiac death occurred (4%) over a mean postoperative follow-up period of 32 months. At follow-up 63% were free of angina. The reasons for late surgery were (1) progressive angina, 80%; (2) recurrent unstable angina, 10%; and (3) other reasons, 10%. Entry characteristics were compared for patients who adhered to medical treatment and medical crossovers to surgery. At entry medical patients who crossed over to surgery

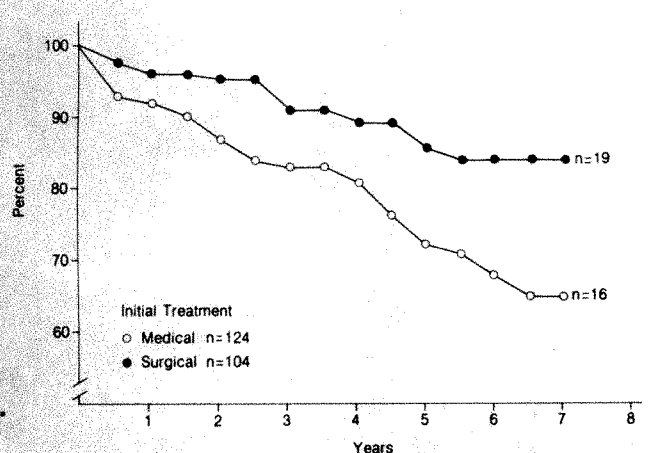

FIGURE 1. Survival curves for patients according to initial treatment. Mantel-Haenszel test at 7 years, p = 0.012.

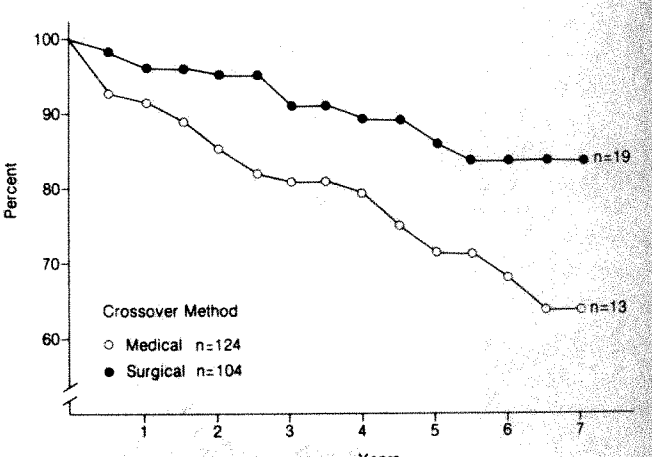

FIGURE 2. Survival curves for patients analyzed by crossover method (medical patients included only to the date of surgery). Total deaths. Mantel-Haenszel test at 7 years, p = 0.008.

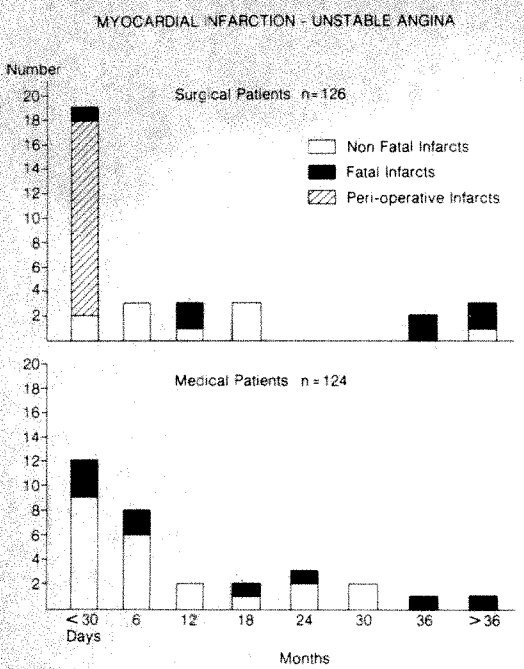

FIGURE 3. Fatal, nonfatal, and perioperative myocardial infarction. Crossovers are included in the surgical group from the date of surgery.

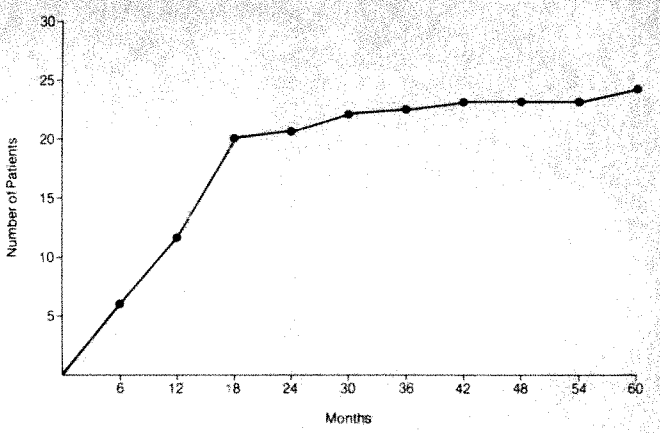

FIGURE 4. Time of surgery in medical crossover patients from the date of entry.

had a higher incidence of the following characteristics than those who adhered to medical therapy: (1) prior myocardial infarction (70 versus 44%); (2) level of serum creatinine kinase elevation during the initial 3 days of hospital observation (121 versus 66 units); (3) shorter duration of treadmill exercise (273 versus 369 seconds); (4) 3 vessel coronary disease (60 versus 43%); and (5) left ventricular contraction abnormalities demonstrated by angiography (72 versus 60%).

Cause and mode of death (Table XIII): Sudden death was more common in the medical group.

Risk factor analysis: Risk factors were evaluated in all patients who died (Table XIV, Fig. 5). The following entry descriptors were more common in patients who died than in survivors: age greater than 60 years, diastolic blood pressure greater than 89 mm Hg, S-T depression, S-T elevation, 3 vessel coronary disease, left main coronary disease, and an elevated left ventricular diastolic pressure at rest and during exercise. No patient who died had single vessel coronary disease.

* Percent of all deaths.
† Death within 24 hours of the onset of symptoms outside the hospital.

Discussion

This study shows that surgical treatment of unstable angina is accompanied by a moderate improvement in survival compared with medical treatment. This is apparent even when patients with left main coronary disease are excluded. It is not significantly altered when total deaths are counted compared with cardiac deaths. The influence of medical crossovers does not appear to be responsible for the difference.

Randomized studies of medical versus surgical treatment of stable angina have reported no difference in survival in medically treated patients and patients who had surgery when the total study group was evaluated.[1-4,7-10] If high risk subgroups are defined 3 groups appear to demonstrate improved survival on surgical treatment: (1) patients with left main coronary disease; (2) patients with the following noninvasive risk factors: S-T segment depression in the resting electrocardiogram, history of myocardial infarction, history of hypertension, and New York Heart Association functional class III or IV[10]; and (3) patients with 3 vessel coronary disease and some abnormality of left ventricular function.[9]

Using a data bank-matching method Hammermeister et al.[12] have shown that patients with 2 vessel disease and a reduced ejection fraction also have improved survival with surgical treatment.

Controlled studies of unstable angina have contained an insufficient number of patients to examine survival in subgroups. However, it seems likely that medically treated unstable angina is associated with a higher mortality than medically treated stable angina. The 2 year mortality rate in patients with nonleft main coronary disease with stable angina in the Veterans Administration Cooperative Study medical group was 8%. In the present study the mortality rate was 18.5%. Data

TABLE XIV Risk Factors in Survivors Compared With Nonsurvivors

	Survivors (195)		Nonsurvivors (33)

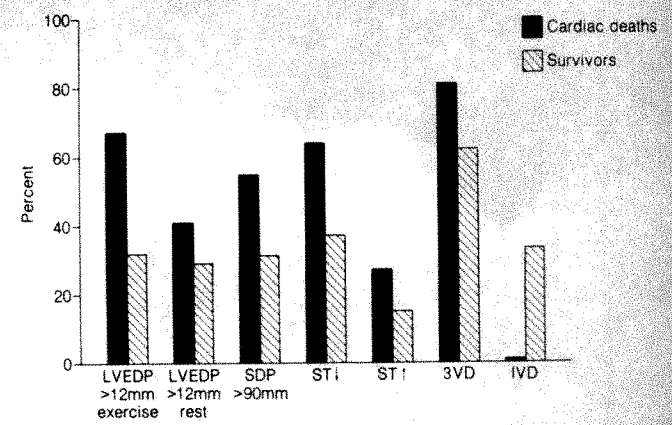

FIGURE 5. Differences between cardiac deaths and survivors. LVEDP = left ventricular end-diastolic pressure; SBP = systolic blood pressure at entry; ST↓ = S-T segment depression on electrocardiography at entry; ST↑ = S-T segment elevation; 3VD = 3 vessel disease; 1VD = 1 vessel disease.

bank studies at Duke University have shown that progressive angina was associated with a higher mortality in patients on medical treatment than in those with stable angina.[12] In Hammermeister's patient group which showed improved survival with surgical therapy in subgroups, 40% had progressive or probable unstable angina. For these reasons an improvement in survival by surgical therapy is not unexpected in patients with unstable angina.

The present study confirms nearly all of the findings of the Cooperative Unstable Angina Study Group (MIRU) except in comparative survival. Comparison of the essential entry features of patients in the MIRU Study and those in the present study reveals very few significant differences.[2,3] This suggests that the MIRU Study group was representative of patients with unstable angina. The difference in survival does not appear to be due to differences in surgical skill because in both studies the operative mortality rate was low and the total morality rate in the surgical group was essentially the same (8 versus 10%). The principal difference was a high mortality in the medical group in the present study (18.5%), versus 9% in the MIRU Study ($p < 0.05$). The high incidence of crossovers and the short follow-up time in the MIRU Study limited the evaluation of comparative survival data.

The present study can be criticized because it was not a prospective randomized study. If randomization had been employed it is very doubtful that a sufficient number of patients would have been entered to achieve any significant data. The acceptability of a data bank approach has been demonstrated by other workers.[12,13] However, these studies have the weakness of being retrospective studies, and the selection of patients is based on the coronary arteriograms. The present study has avoided these problems by being a prospective study with patients selected on the basis of well-defined, objective entry criteria.

A limitation of the study is that only 65% of the medical patients had arteriography. It might be argued that the patients without angiography had more severe disease than those who had angiography, thus introducing a bias in favor of surgical therapy. To examine this possibility the 44 medical patients without angiography were compared with the 80 medical patients who had angiography. Noninvasive entry characteristics including the results of treadmill tests were similar in the 2 groups. The 5 year mortality rate was essentially the same in patients who did not undergo angiography (39%) as in patients who had undergone angiography (43%). The symptomatic status at 5 years was similar in both groups. For these reasons it is unlikely that the patients without angiography had biased the follow-up results.

Three aspects of the management of unstable angina deserve final comments in view of the results of this study:

1. Prevention of myocardial infarction: The low incidence of intrahospital infarction during the initial cooling off period may well be due to the intensive medical therapy with beta-adrenergic blocking agents and nitrates. This therapy is now generally accepted. The incidence of perioperative infarction has been reduced significantly in our hospital over the last 5 years, and the current incidence in patients with unstable angina is 3.0%. Thus with modern methods of myocardial protection the total incidence of infarction in surgically treated patients may become substantially lower than one would expect from medical treatment alone. The mean interval from hospital admission to surgery in the present study was 15 days. The incidence of perioperative infarction may be reduced by a longer waiting period between the onset of unstable angina and surgery. No data are available to support this possibility, but information for large scale studies should be examined with this possibility in mind.

2. Improvement in survival: Although overall survival in unstable angina appears to be improved by surgery as suggested by the present study, high risk subgroups of patients will probably exhibit the most striking improvement in survival. In stable angina such high risk groups can be identified by noninvasive methods.[10] The present study suggests that improved survival will probably be evident in patients over age 60 years who

have diastolic hypertension and ST-T wave changes in the resting electrocardiogram. Invasive features of high risk patients are 3 vessel coronary disease and elevated left ventricular end-diastolic pressure at rest and during exercise (pulmonary arterial wedge pressure). Patients with single vessel disease should be considered surgical candidates only for relief of symptoms.

3. Relief of symptoms and medical treatment failures: Is it possible to predict medical treatment failures from entry characteristics? The present study suggests that the following features were more commonly observed in patients who failed to obtain optimal symptom relief on medical therapy and subsequently had late surgery: prior infarction, poor treadmill performance, serum creatine kinase elevation, 3 vessel disease, and left ventricular contraction abnormalities.

It is hoped that further studies such as the current Veterans Administration Cooperative Study of Unstable Angina will provide an opportunity to examine critically these possibilities.

Addendum

Additional follow-up of all patients up to July 1981 revealed 11 additional deaths in the medical group and 4 additional deaths in the surgical group, indicating a continuing trend toward better survival in the surgical group.

Characteristics of Survivors of Exertion- and Nonexertion- Related Cardiac Arrest: Value of Subsequent Exercise Testing

W. DOUGLAS WEAVER, MD, LEONARD A. COBB, MD, and ALFRED P. HALLSTROM, PhD

Ninety ambulatory patients previously resuscitated from out-of-hospital ventricular fibrillation underwent treadmill exercise testing an average of 11.5 months after the episode. The level of physical activity immediately before cardiac arrest was known in 86 patients: 23 (27%) had had ventricular fibrillation in association with exertion and 63 (73%) while performing low level activity. Prodromal chest pain and evidence of acute myocardial infarction occurred in a similar proportion of both activity groups. Subsequent exercise test results showed few differences between the groups. Angina occurred in only 11 patients and exercise evoked "ischemic" S-T change in less than half of each group. More of the patients who had collapsed during nonexertional activities had exercise-evoked complex ventricular arrhythmias than did patients who had collapsed during exertion: 33 (52%) versus 6 (26%), respectively ($p < 0.05$).

The 90 patients were followed up for 2 or more years. At 24 months of follow-up, there were 27 deaths of which 19 were due to unexpected cardiac arrest. Only 2 findings on exercise testing were associated with subsequent fatal events. Seven of 11 patients (64%) who had angina during testing had cardiac arrest or died, compared with 20 patients (25%) who had stopped for other reasons ($p < 0.01$). Failure of systolic arterial pressure to rise 10 mm Hg or more during the test was also associated with poor survival: respective mortality at 2 and 4 years was 54 and 69% in those with this abnormal response, compared with 26 and 42% at 2 and 4 years in those whose pressure rose normally ($p < 0.004$).

In the majority of patients ventricular fibrillation developed at low activity levels, and no characteristics were found unique to those who collapsed during exertion. Routine exercise testing was of limited value in the assessment of patients previously resuscitated from cardiac arrest. Exercise-evoked angina and systolic hypotension were highly associated with outcome; however, their ability to predict survival for individual patients was only modest.

In Seattle, approximately 100 victims of out-of-hospital cardiac arrest are resuscitated and ultimately discharged from the hospital each year.[1] Earlier reports showed that most survivors have a history of cardiovascular disease[2] and that about 20% develop evidence of acute transmural myocardial infarction in association with ventricular fibrillation.[3] The majority of survivors have 2 or 3 vessel coronary disease, and many demonstrate marked left ventricular contraction abnormalities, both of which are strongly associated with subsequent episodes of cardiac arrest.[4]

The mechanisms causing ventricular fibrillation are probably multiple. Sudden cardiac arrest may occur during or after vigorous physical exertion; more commonly it is an unexpected event during sedentary activity. In this study, we examined the clinical characteristics of 90 patients with coronary heart disease who had been resuscitated from ventricular fibrillation and who also had subsequent symptom-limited treadmill exercise testing. We compared the clinical findings and

results of exercise testing in patients who had developed ventricular fibrillation in association with exertion with the group who had collapsed while sedentary or while engaged in minimal physical activity. Through these comparisons we sought to examine relationships among physical exertion, acute myocardial ischemia, and sudden cardiac death.

Methods

Patients: Ninety patients previously resuscitated from ventricular fibrillation by the Seattle Fire Department's emergency care system participated in the study. All had coronary heart disease on the basis of typical clinical or laboratory data, that is, a history of angina or heart attack, electrocardiographic criteria of transmural myocardial infarction, or coronary angiography. Patients with other heart diseases were excluded from this study, as were a small number with no evident heart disease. Coronary angiography was performed in 35 (39%) of the patients at the discretion of the patient's personal physicians.

Level of physical activity before cardiac arrest: The level of physical activity immediately before collapse and cardiac arrest could be determined in 86 patients through interviews with the patient or witnesses to the episode of cardiac arrest. Interviews were done shortly after the arrest, usually within 1 month. Activities were categorized as (1) sedentary, (2) ambulatory, or (3) exertional. Exertion included: participation in active sports, vigorous exercise, dancing, or heavy manual work. Ambulatory activities included walking, standing, or personal hygiene. Bed rest and sitting were classified as sedentary activities. This activity level at the time of cardiac arrest was used to determine an arrest related to exertion and to nonexertion (sedentary or low level activity). Activity level was not determined by overall evaluation of physical training of the victims.

Clinical evaluation and exercise testing: All patients volunteered to participate in a special research clinic after hospital discharge. About 70% of patients resuscitated from out-of-hospital cardiac arrest attend this clinic. It is not possible to be certain whether patients in this report were representative of all victims resuscitated. They may be more motivated or inquisitive and less physically disabled than those who chose not to participate.

A physician interviewed the patient, performed a physical examination, and reviewed the postresuscitation hospital record at the first clinic visit. Disability was assessed at that time using New York Heart Association criteria.[5] If there were no clinical contraindications and if the patient and his personal physician agreed, a multistaged treadmill test was done.[6] Elapsed time from cardiac arrest to exercise testing averaged 11.5 (±12.5 standard deviation) months. Fifty-eight (64%) were tested within 1 year of the event. Results of those tested within 1 year and later were also compared to unmask any possible bias toward outcome.

The duration of treadmill exercise was determined by the patient, who was instructed to stop when limiting symptoms of fatigue, chest pain, shortness of breath, or lightheadedness occurred. Blood pressure was measured by standard cuff technique during the midportion of each exercise level. Cardiac rhythm, heart rate, and S-T segment response were monitored continuously by the oscilloscope and recorded each minute. A single modified V_5 electrode was used.[7] Unsteady gait, fall in systolic blood pressure, increasing ventricular arrhythmia, or evoked complex ventricular arrhythmias were additional indications to stop the test. During the postexercise recovery period, the blood pressure, rhythm, and S-T response were recorded at least every minute for 5 minutes, or until exercise-induced symptoms or electrocardiographic abnormalities resolved. In 23 patients the S-T segment was depressed during the resting tracing in association with digoxin or conduction abnormalities. Accordingly, this group was excluded from further exercise S-T analysis.

Clinical characteristics and exercise test responses were compared in 2 groups of patients: (1) those in whom ventricular fibrillation occurred in association with exertion, and (2) those who developed cardiac arrest while performing sedentary or low levels of activity. Differences in discrete variables were analyzed by the chi-square test and in continuous variables by Student's *t* test. We looked for possible interrelationships between activity group, outcome, time from arrest until exercise testing, and exercise test results using analysis of variance. Survival analyses were done using the product limited method.[8]

Follow-up: All ninety patients were followed up at least 2 years; the average follow-up was 4 years. By 2 years of follow-up, 19 patients (21%) had had unexpected fatal cardiac arrest (n = 15) or were resuscitated from another episode of out-of-hospital ventricular fibrillation (n = 4). Eight others had nonsudden death, usually occurring during a subsequent hospitalization for myocardial infarction or heart failure. Thus, there were 27 fatal events at 2 years. The findings of exercise testing in survivors were compared with the findings in those who died or developed cardiac arrest.

tients (73%) had cardiac arrest while sedentary or during low level physical activity. The average ages of the 2 groups were 59.5 and 60.9 years, respectively. All patients in the exertion group were men, whereas 10 of 63 patients in the nonexertion group were women. During the postresuscitation hospitalization, electrocardiographic (new Q waves) or lactic dehydrogenase isoenzyme evidence of acute myocardial necrosis (LDH_1 increased and greater than LDH_2) developed in about one third of all patients; these findings were present in 7 patients in the exertion group (30%) and in 23 of the nonexertion patients (37%). Immediately before cardiac arrest, chest pain was present in 4 patients (27%) who had had ventricular fibrillation during exertion and in 18 (29%) of the nonexertion group. Of the 22 patients who had chest pain preceding cardiac arrest, acute myocardial infarction developed in all 4 of those who collapsed with exertion and in 8 of 18 in the nonexertion group.

The prevalence of individual cardiovascular characteristics (history of either angina, remote myocardial infarction, hypertension, or congestive heart failure) was similar for both patient groups. However, if the histories were considered conjointly, fewer of the patients who had ventricular fibrillation in association with exertion had prior manifestations of cardiovascular disease, compared with those in the nonexertion group (57 versus 79 percent, $p < 0.05$).

The clinical history before cardiac arrest suggested that patients who collapsed during exertion also had less physical disability than did those who collapsed while sedentary. Moderate to severe physical impairment (functional class 3 or 4) was present in 4 patients (17%) in the exertion group compared with 26 (41%) in the nonexertion group ($p < 0.05$).

Exercise test results (Tables II and III): Patients who had developed ventricular fibrillation during exertion tended to exercise longer than did patients in the nonexertion group: 5.6 ± 0.6 (mean ± standard error of the mean) minutes compared with 4.4 ± 0.3 minutes ($p < 0.1$). The reasons for stopping the test were similar in both groups. Angina was induced infrequently; it was the primary reason for terminating the exercise test in only 7 patients (8%) and occurred as a secondary reason in 4 others. Two patients (9%) in the exertion group developed chest pain during the exercise test; neither had had chest pain immediately before cardiac arrest. Leg or generalized fatigue was the usual reason for stopping in nearly three fourths of patients. The attending physician interrupted the test in 10% of patients because of either increasing or complex ventricular arrhythmia. In an additional 21 patients (25%), ventricular arrhythmia was listed as a secondary reason for stopping. In 6 other instances, the test was also terminated by the physician because of concern about the patient's poor physical performance or a fall in blood pressure during exercise testing (Table II). Thus, 36 patients (40%) developed either electrocardiographic or hemodynamic findings that prompted discontinuation of the test.

There were no significant differences between the 2 activity groups in the mean peak heart rate or systolic blood pressure attained during exercise testing. However, more of the exertion group (91%) reached a

peak rate of 130 beats/min or greater than did the patients who had previously collapsed while sedentary (38%). Systolic blood pressure also tended to increase more in the patients with previous exertion-related cardiac arrest.

Ventricular arrhythmias were observed in 64% of patients during exercise or recovery. We did not determine possible serum antiarrhythmic drug levels, and no attempt was made to control for the use of these drugs, which were being taken by half of the patients. Exercise-evoked complex ventricular arrhythmia (bigeminy/trigeminy, multiform beats, or repetitive beats) occurred in a greater proportion of the patients who had collapsed while sedentary than of those who collapsed during exertion: in 33 (52%) versus 6 (26%), respectively ($p < 0.05$). Seven episodes of paroxysmal self-limited ventricular tachycardia occurred (4 or more repetitive beats), all in the nonexertion group.

An "ischemic" S-T segment response (1 mm or more of flat or downsloping depression) developed during or after exercise testing in 28 of 63 tests (44%) in which interpretation was possible. There was no difference in the proportion of the 2 activity groups who developed "ischemic" S-T responses. In addition, we examined the activity groups and exercise test results in patients who were tested within 6 months, 1 year, and more than 1 year after cardiac arrest. The duration from arrest until testing had no significant effect on any of the findings.

Exercise testing and subsequent outcome (Table IV): The overall mortality rates at 1, 2, and 4 years were 20, 30, and 46 percent, respectively. By 2 years after the exercise test, there were 19 unexpected cardiac arrests and 8 additional nonsudden deaths. Survival was similar in the exertion- and nonexertion-related groups. Eight of the patients in the exertion-related group and 15 of those in the nonexertion-related group died. Also, outcome in these 2 groups of patients was not related to the time from cardiac arrest until exercise testing.

Neither the change in heart rate, peak heart rate, and duration of treadmill exercise, nor evoked S-T depression or arrhythmias was related to subsequent sudden or nonsudden death, irrespective of the time from previous arrest to testing. Only 2 observations during the index exercise test were associated with subsequent fatal events: angina and exertional hypotension. Although angina was evoked in only 11 patients, 7 (64%) had a fatal event by the end of 2 years. In contrast, 20 of 79 patients (25%) who stopped the test for other reasons had a recurrent cardiac arrest or nonsudden death ($p < 0.01$) (Fig. 1). Exercise limitations other than chest pain were not related to outcome.

Failure of the systolic blood pressure to increase to 10 mm Hg or more during treadmill exercise was observed in 13 patients and was also associated with poor survival (Fig. 2). The survival rates over the first 4 years were 82, 74, 68, and 58%, respectively, in patients whose blood pressure rose normally compared with 62, 46, 38, and 31% in those whose blood pressure failed to rise ($p = 0.004$). This relationship was valid whether the test

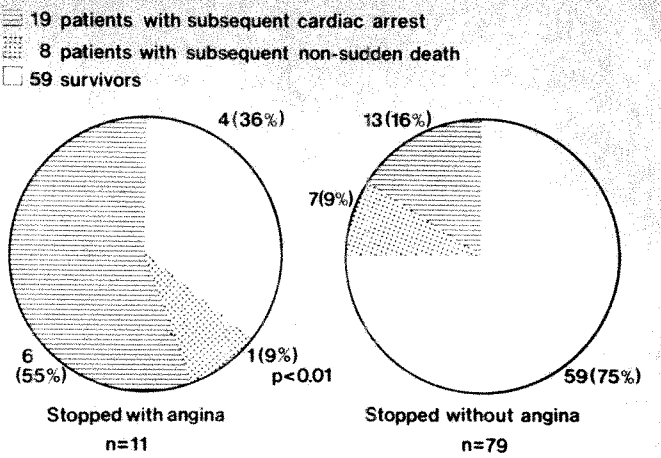

FIGURE 1. Mortality at 2 years of follow-up was greater if angina had occurred during exercise testing. Sixty-four % of those who had angina during testing (**left**) had a subsequent fatal event, compared with 25% of those who had stopped the test for other reasons (**right**) ($p < 0.01$).

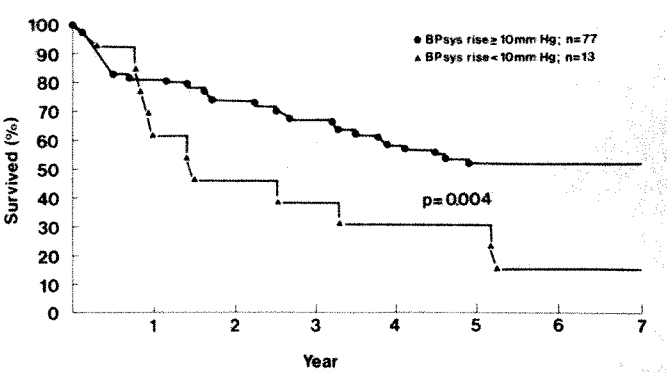

FIGURE 2. Failure to augment systolic blood pressure (BP sys) by 10 mm Hg or more during exercise was associated with significantly worse survival. There were more subsequent sudden and nonsudden deaths in patients whose blood pressure failed to increase normally. Seventy-four % of patients who had a normal response were alive at 2 years, compared with 46% of those in whom exertional hypotension had developed.

had been done within 6 months, 1 year, or longer from the initial event and was unrelated to any of the other observations made during exercise. Only 1 patient exhibited both angina and an impaired augmentation of systolic pressure during the test. By 2 years, 14 of 23 patients (61%) with either of these findings had died, compared with 13 deaths in the 67 patients (19%) not having these findings. At 4 years of follow-up 20 (87%) of this abnormal test group had died, compared with 43% of patients without either of these exercise-evoked findings ($p < 0.0001$).

Despite the strong association between subsequent mortality and exercise-evokd angina or abnormal blood pressure response, the value of these findings as predictors of subsequent cardiac arrest and death was

limited. The sensitivity, specificity, and predictive accuracy of evoked angina were 26, 94, and 64%, respectively; and for abnormal systolic pressure increase they were 25, 90, and 54%, respectively.

Discussion

Exertional versus nonexertional cardiac arrest: Twenty-seven percent of our 90 patients, all previously resuscitated from out-of-hospital cardiac arrest, had ventricular fibrillation in association with physical exertion. A similar incidence of exertion-related cardiovascular collapse was reported in another group of resuscitated victims[9] and by registries[10,11] which examined the circumstances associated with instantaneous out-of-hospital death. We had anticipated differences in the clinical characteristics of patients who developed cardiac arrest in association with exertion compared with those who collapsed at low activity levels. However, there were few such differences: symptoms of chest pain just before cardiac arrest, evidence of acute infarction, and development of angina or ischemic S-T responses during subsequent treadmill testing were present in similar proportions of both groups. Clearly, cardiac arrest develops in some patients during or after exertion. During supervised exercise in a Seattle area cardiac rehabilitation program, 23 patients collapsed with cardiac arrest; all had ventricular fibrillation and all were resuscitated.[12,13] Our observations suggest that exertion-related ventricular fibillation is not usually the result of acute infarction. There was also no evidence during subsequent exercise testing of more exertion-evoked ischemia or arrhythmias in patients who had previously collapsed during exertion than in those who had collapsed while sedentary.

Angina and decrease in systolic pressure during exercise testing as predictors of survival: Only 2 findings during exercise testing were associated with a subsequent fatal event. Both sudden and nonsudden death occurred more frequently in patients who had angina during the exercise test, compared with those who stopped the test for other reasons. Also, failure of systolic blood pressure to increase 10 mm Hg or more during stress testing was an unfavorable prognostic sign. "Exertional hypotension" thus may not only portend ventricular fibrillation *during* exercise testing and serve as an indication for stopping the test,[14] but also is prognostic of a subsequent fatal event. Both findings, however, were only modest predictors of outcome. Fourteen of 27 patients who had died by 2 years had either exercise-evoked angina or hypotension (sensitivity 52%, specificity 86%, predictive accuracy 61%).

As our purpose was to examine possible mechanisms of cardiac arrest in activity groups using a noninvasive test and also to use standard exercise testing as a predictor of outcome, we did not regularly perform angiography as a part of this study. We suspect that exertional hypotension and angina occurring in these patients probably results from either severely impaired ventricular function due to previous infarction or to ischemia associated with severe 3 vessel coronary disease. It seems likely that resuscitated patients who develop angina or hypotension during the subsequent exercise testing have these angiographic findings, both of which are associated with subsequent cardiac arrest.[4] It is our present recommendation that cardiac catheterization be performed and coronary bypass surgery considered in suitable candidates who show these exercise abnormalities after resuscitation.

Prognostic role of exercise-induced ventricular arrhythmia: Ventricular arrhythmias evoked during or after exercise were not predictive of subsequent mortality. Complex ventricular arrhythmias occurred in slightly less than half of both survivors and nonsurvivors. This incidence of exercise-induced arrhythmia is similar to other observations during exercise testing of patients with recurrent paroxysmal ventricular tachycardia,[15] but somewhat greater than that found in patients in general with known coronary heart dis-

ease.[16–20] Others[21–23] have suggested that exercise-evoked ventricular arrhythmias in the setting of ischemic heart disease is associated with subsequent sudden death. There are several possible reasons for the apparent discrepancy between those reports and our own. First, our observations concern a select group of patients: all have had a previous episode of out-of-hospital ventricular fibrillation. Second, both of our subsequent outcome groups had a high incidence of exercise-evoked complex arrhythmias compared with that in other studies of patients with coronary heart disease. Additionally, we did not discontinue antiarrhythmic treatment before testing. This may have favorably affected the rhythm, although a similar proportion of both survivors and nonsurvivors were taking these drugs. Although the other reports did demonstrate a statistical association between outcome and exertional arrhythmias, the predictive accuracy was poor and the finding was of limited value in estimating prognosis for a given patient. In view of our findings reported here and those mentioned earlier, we do not feel that exercise-evoked arrhythmias have major prognostic importance in individual tests; that is, they are neither a highly sensitive nor specific predictor of sudden cardiac death. At present we employ electrophysiologic testing to select antiarrhythmic therapy in appropriate patients regardless of the results of exercise testing.

Implications: Contrary to what might be expected, we found no evidence from exercise testing that patients who had previously had ventricular fibrillation in association with exertion had a greater incidence of either evoked ischemia or ventricular arrhythmia than that observed in patients who had collapsed at low levels of physical activity. The mechanism of exertion-related ventricular fibrillation is still unclear. Exercise-evoked angina and S-T evidence of ischemia were surprisingly unusual during testing of patients previously resuscitated from cardiac arrest, and exercise ventricular arrhythmias were not of prognostic import. Routine exercise testing of these patients is of limited use in predicting the outcome for individual patients. However, exercise-evoked angina and systolic hypotension were highly associated with the occurrence of subsequent fatal events.

Quantitative Comparison of Extent of Coronary Narrowing and Size of Healed Myocardial Infarct in 33 Necropsy Patients With Clinically Recognized and in 28 With Clinically Unrecognized ("Silent") Previous Acute Myocardial Infarction

HENRY SCOTT CABIN, MD and WILLIAM C. ROBERTS, MD

Clinical and necropsy observations are described in 61 patients with a healed transmural myocardial infarction, 33 with and 28 without a clinical history of acute myocardial infarction. There were no significant differences between the 2 groups of patients in mean age, sex, or frequency of angina pectoris, chronic congestive heart failure, systemic hypertension, sudden coronary death, or fatal acute myocardial infarction. Compared with the patients with clinically recognized acute myocardial infarction, the patients with clinically unrecognized (silent) infarction had a significantly ($p < 0.05$) higher incidence of diabetes mellitus (43 versus 15%), death from noncardiac causes (39 versus 9%), posterior (inferior) wall infarcts (82 versus 55%), and smaller infarcts (mean size 7 versus 17% of left ventricular wall). The patients with and without clinically recognized infarction had similar numbers of the 4 major coronary arteries severely (76 to 100% in cross-sectional area) narrowed (mean 2.8 versus 2.9/4.0 per patient), insignificant differences in incidence of severe narrowing of the left main coronary artery (18 versus 29%), similar overall percents of 5 mm segments of the 4 major coronary arteries severely narrowed (43 versus 42%), and similar percents of severely narrowed 5 mm segments of the right (46 versus 55%), left anterior descending (39 versus 33%), and left circumflex (41 versus 41%) coronary arteries.

Some patients with acute myocardial infarction have symptoms and signs indicative of coagulation necrosis of a portion of the left ventricular myocardial wall, and others apparently have no clinical manifestations caused by the myocardial necrosis, that is, the event is clinically silent. Indeed, possibly as many as 50% of acute myocardial infarcts are not recognized clinically.[1-11] Although several previous studies[1-11] have focused on clinically unrecognized acute myocardial infarction, none have compared at necropsy the degrees of coronary arterial narrowing and the extent of the myocardial damage in patients with clinically *recognized* versus those with clinically *unrecognized* acute myocardial infarction that healed. The present study compares the amount of coronary arterial narrowing and left ventricular myocardial scarring in 33 patients with a clinically unrecognized with that in 28 patients with a clinically recognized transmural acute myocardial infarct that healed.

Methods

Study patients: All 61 study patients had a healed transmural myocardial infarct defined as a left ventricular scar involving more than the inner one half of the thickness of the left ventricular wall at any point.[12] For each patient the medical records were reviewed in detail by at least one of us and the patients were divided into 2 groups according to the presence (33 patients) or absence (28 patients) of a clinical history of acute myocardial infarction. Patients were included in the clinically recognized myocardial infarction group (hereafter referred to as the recognized infarct group) if there was a record of hospitalization for acute myocardial infarction with subsequent confirmation of the diagnosis by established electrocardiographic and enzymatic criteria. All 33 patients

had prolonged chest pain at rest. Patients were included in the clinically unrecognized acute myocardial infarction group (hereafter referred to as the unrecognized infarct group) if detailed medical records were available and there was no report of hospitalization for acute myocardial infarction or record of unstable angina pectoris, prolonged chest pain at rest, acute worsening of congestive heart failure or syncope (except within the final 2 months of life). In the patients with unrecognized acute myocardial infarction, electrocardiograms never indicated a pattern consistent with acute myocardial infarction except in the 7 (of 28) patients in whom this event was fatal; all 28 patients, of course, had transmural left ventricular scars. Patients with an equivocal or inadequate history were excluded as were patients with symptoms suggestive of acute myocardial infarction who did not seek hospitalization or who were hospitalized but did not have laboratory confirmation of the diagnosis of acute infarction.

Pathologic examination: In each patient, the heart was cut into 5 or 6 one cm thick transverse ventricular slices from apex to base parallel to the posterior atrioventricular sulcus. The major location of the infarct was determined by identifying the portion of left ventricular wall with the greatest amount of scar. When the infarct was circumferential at the apex, the basal portion of the heart was used to determine the predominant location of the infarct. In all but 3 of the 61 patients the infarct was located predominantly in the anterior

or posterior wall with or without involvement of the ventricular septum or lateral wall (defined as that portion of left ventricular wall between the lateral borders of the anterolateral and posteromedial papillary muscles).

The percent of myocardium replaced by scar was determined by tracing the grossly visible areas of scar and the total left ventricular area including ventricular septum (with compensation for wall thinning in areas of scar) from photographs of the apical surfaces of each transverse ventricular slice. The area of scar and the total left ventricular area were then determined by a videoplanimetry system. The sum of the areas of scarring divided by the sum of the left ventricular areas provided the infarct size expressed as a percent of total left ventricular area.

In each of the 61 patients, the entire lengths of the right, left main, left anterior descending, and left circumflex coronary arteries were removed from the heart intact, fixed in an unpressurized state in 10% formalin for about 48 hours, radiographed, and if calcific deposits were present, decalcified. Then each of the 4 major arteries was cut transversely into 5 mm long segments, processed in alcohol and xylene and cut. At least one 6 μm thick section from each 5 mm segment was prepared for histologic study and stained by the Movat method.[13] The degree of luminal narrowing in each 5 mm long segment was determined by microscopic examination at a magnification of 25 to 50 times. The percent of cross-sectional area narrowing by atherosclerotic plaque was divided into 5 categories of narrowing: 0 to 25, 26 to 50, 51 to 75, 76 to 95, and 96 to 100. The accuracy of these determinations was verified by videoplanimetry and shown to have an error of less than 5 percent.[14]

Statistical analysis: The unpaired and paired Student's *t* test was employed for the quantitative comparisons of coronary narrowing. Chi-square analysis was utilized for comparison of clinical variables and for comparison of amounts of coronary narrowing by qualitative means.

Results

Clinical findings (Table I): Angina pectoris occurred in 14 (42%) of the 33 patients in the recognized infarct group (after the infarct in each) and in 6 (21%) of the 28 patients in the unrecognized infarct group ($p < 0.10$). Diabetes mellitus of adult onset occurred more frequently in the unrecognized than in the recognized infarct group (12 [43%] versus 5 [15%]) ($p < 0.05$). Among the 17 patients with diabetes mellitus, angina pectoris was present in 4 of the 12 patients with clinically unrecognized infarcts and in 2 of the 5 patients with recognized infarcts. Death from noncardiac causes occurred more often in the unrecognized infarct group (11 [39%] versus 3 [9%]) ($p < 0.01$).

Location and size of infarct (Table II): The predominant location of the healed myocardial infarct was the anterior wall of the left ventricle in 16 (48%) of 33 patients from the recognized infarct group and in 5 (18%) of 28 from the unrecognized infarct group ($p < 0.01$); posterior wall in 15 (45%) and 22 (79%), respectively ($p < 0.025$); lateral wall in 1 (3%) and none, respectively (p = NS); and ventriculum septum in 1 (3%) and 1 (4%), respectively (p = NS). The percent of left ventricular myocardium (including ventricular septum) infarcted ranged from 1 to 55 (mean 17) in the recognized infarct group and from 1 to 23 (mean 7) in the unrecognized infarct group ($p < 0.001$).

Incidence of severe coronary narrowing (Tables III and IV): Of the 132 major (right, left main, left anterior descending, and left circumflex) epicardial coronary arteries examined in the 33 patients in the recognized infarct group, at least one 5 mm segment in 93 (70%) arteries was narrowed severely (76 to 100% in cross-sectional area) by atherosclerotic plaques, an average of 2.8 of 4.0 coronary arteries per patient; of the 112 major coronary arteries examined in the 28 patients in the unrecognized infarct group, 81 (72%) were so narrowed, an average of 2.9 of 4.0 coronary arteries per patient (p = NS). No significant difference was observed in the numbers of patients with severe narrowing of any of the 4 major arteries, or in the numbers of patients with 0 to 4 of the 4 major coronary arteries severely narrowed.

Quantitative analysis of amount of narrowing in 2,705 five mm long segments of the right, left anterior descending, and left circumflex coronary arteries (Fig. 1 and 2): Of the 1,443 five mm segments in the 33 patients in the recognized infarct group, 167 (12%) were narrowed 96 to 100% in cross-sectional area by atherosclerotic plaque; 444 (30%) were narrowed 76 to 95%; 519 (36%), 51 to 75%; 230 (16%), 26 to 50%; and 84 (6%), 0 to 25%. Of the 1,262 five mm segments of coronary artery in the 28 patients in the unrecognized infarct group, 91 (7%) were narrowed 96 to 100%; 461 (36%) were narrowed 76 to 95%; 374 (30%), 51 to 75%; 197 (16%), 26 to 50%; and 139 (11%), 0 to 25% (Fig. 1). There was no significant difference between the 2 groups in any of the 5 categories of cross-sectional area narrowing.

Within the recognized infarct group there was no significant difference in the percent of 5 mm segments of coronary artery with severe narrowing among the left anterior descending, left circumflex, or right coronary arteries (39, 41, and 46%, respectively) (Fig. 2). In the unrecognized infarct group, however, the right coronary artery had a significantly greater percent of 5 mm segments narrowed severely than the left anterior descending ($p < 0.02$) and left circumflex coronary arteries ($p < 0.03$) (55, 33, and 41%, respectively). There was no significant difference between the 2 groups in the per-

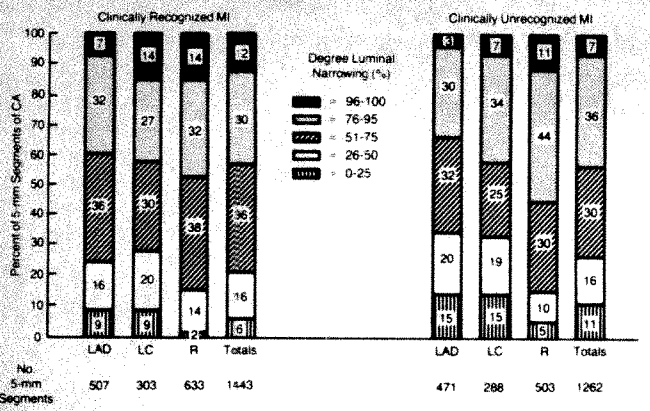

FIGURE 1. Percent of 5 mm segments of the right (R), left anterior descending (LAD), and left circumflex (LC) coronary arteries (CA) narrowed to various degrees by atherosclerotic plaque in 33 patients with clinically recognized and in 28 patients with clinically unrecognized acute myocardial infarction (MI) and healed transmural infarction at necropsy.

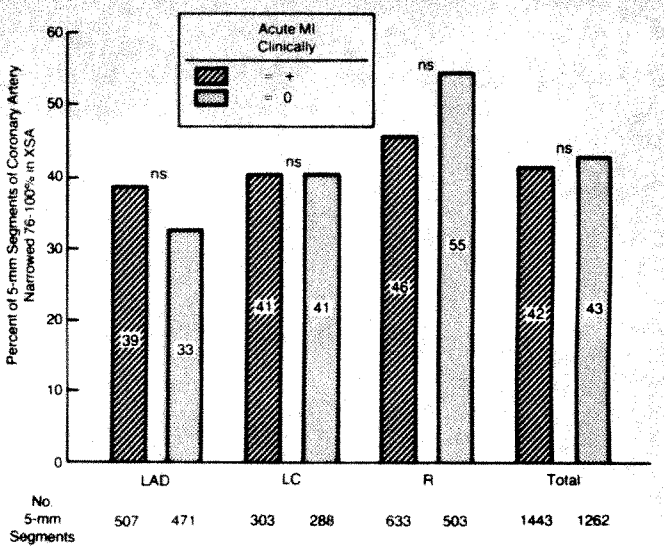

FIGURE 2. Percent of 5 mm segments of the right (R), left anterior descending (LAD), and left circumflex (LC) coronary arteries narrowed 76 to 100% in cross-sectional area (XSA) by atherosclerotic plaque in 33 patients with and in 28 patients without a clinical history of acute myocardial infarction (MI) and a healed transmural infarction at necropsy.

cent of 5 mm segments narrowed severely in each of the 3 major coronary arteries.

A scoring system was utilized to indicate both the severity and extent of coronary narrowing. Every 5 mm long segment of coronary artery from each patient was assigned a score of 1 to 4 based on the amount of cross-sectional area narrowing by atherosclerotic plaque as follows: 1 = 0 to 25% narrowing; 2 = 26% to 50%; 3 = 51 to 75%; and 4 = 76 to 100%. A total score was obtained for each patient and the score per 5 mm segment was then calculated by dividing the total score per patient by the number of 5 mm segments examined from the patient. The scores per 5 mm segment ranged from 1.8 to 3.9 (mean 3.2) in the recognized infarct group and from 1.9 to 3.7 (mean 3.1) in the unrecognized infarct group (p = NS).

Comments

Considerable controversy exists regarding the incidence and, in fact, the very existence of the entity that has been variously referred to as *unrecognized silent, undiagnosed, painless, asymptomatic,* or *inapparent* myocardial infarction. Some investigators[11,15] have suggested that a careful history taken within a short time of the acute myocardial infarct from a "... nonpsychotic, nonsenile, and nonmedicated..." individual will always disclose some symptom that in retrospect indicates that infarction had occurred. Necropsy studies have been particularly questioned because of the utilization of historic material obtained by nonprimary physicians who usually had not carefully questioned the patient about symptoms referable to the cardiovascular system.

Because of these difficulties, in the present analysis necropsy patients with healed transmural myocardial infarct were divided into clinically recognized and clinically unrecognized infarct groups by asking the question: was there a clinical history of hospitalization for suspected acute myocardial infarction with subsequent laboratory confirmation? Patients in whom this was the case were included in the recognized infarct group. The history of the remaining patients was further analyzed to exclude from the unrecognized infarct group those patients who reported some clinical event with or without hospitalization (such as change in pattern of chest pain, or acute worsening of congestive heart failure or syncope) that occurred more than 2 months before death that might have represented an atypical yet symptomatic acute myocardial infarction. Obviously, the latter analysis is still subject to variability in history-taking and history-giving abilities, patient recall, and variability in a patient's symptom threshold and does not exclude the stoic patient who for whatever reason does not report his symptoms or seek hospitalization. With these reservations in mind and by excluding all patients with an equivocal or inadequate history, we believe it valid to determine whether the 2 groups of patients just defined differed in clinical or necropsy findings, with particular emphasis on infarct size and location and amount and extent of coronary narrowing.

Clinical differences between clinically recognized and unrecognized infarct group: Previous studies have suggested that patients with clinically unrecognized compared with those with clinically recognized acute myocardial infarction have angina pectoris less frequently and that patients with angina pectoris rarely have clinically unrecognized infarcts.[2,3,5-7] In the present study, 21% of the patients in the unrecognized infarct group had typical angina pectoris compared with 42% of those in the recognized infarct group. This difference approached but did not achieve statistical significance ($0.05 < p < 0.10$). In ad-

dition, the incidence of fatal acute myocardial infarction was similar in both groups (25 and 24%, respectively). Thus, patients with a clinically unrecognized acute myocardial infarction that healed had an incidence of symptomatic myocardial ischemic events (fatal acute infarction or angina pectoris) which did not differ significantly from that in patients in whom the acute myocardial infarction was clinically recognized.

Some [5,7,16,17] but not all[2] investigators have reported an association between diabetes mellitus and clinically unrecognized or painless acute myocardial infarction. The present study supports that relationship by showing a significantly increased incidence of diabetes mellitus among the patients in the unrecognized infarct group (43%) compared with those in the recognized infarct group (15%).

Differences in location and extent of infarction: Johnson et al.[2] reported that subendocardial infarcts were less often clinically recognized than transmural infarcts. In addition, they found that among patients with subendocardial infarcts, those in the lateral and posterior walls of the left ventricle were less often recognized than those involving the anterior wall, and among patients with transmural infarcts, those in the lateral wall were less often clinically recognized than those in the anterior or posterior walls. These results are difficult to compare with those in the present study because of differing definitions of the terms *subendocardial* and *transmural* and differing methods of describing infarct locations. The present study includes only patients with healed transmural myocardial infarcts (involving greater than 50% of the thickness of the left ventricular wall at any point), which includes many patients who according to the definitions used by Johnson et al.[2] would be considered to have subendocardial infarcts (involving ". . . predominantly [*but not exclusively*] the endocardial half of the left ventricle"). In our necropsy experience, healed myocardial infarction limited to the endocardial half of the left ventricular wall is unusual, and if the infarct involves any portion of the epicardial half of the wall in addition to involvement of the subendocardial half, we consider it transmural. In addition, all but 3 of our 61 patients had infarction predominantly involving the anterior or posterior wall of the left ventricle with or without involvement of the lateral wall or the ventricular septum. Anterior wall infarction was significantly more common in the patients with recognized than unrecognized infarcts (48 versus 18%), while posterior wall infarction was more common in patients with unrecognized than in those with recognized infarcts (79 versus 45%). Among patients with clinically recognized infarction, the incidence of anteriorly and posteriorly located infarcts was similar (48 and 45%), while among those with clinically unrecognized infarction, posteriorly located scars were far more common than anteriorly located scars (79 versus 18%).

The size of the myocardial infarct in patients with unrecognized versus those with recognized infarct has not been previously reported. The mean percentage of left ventricular wall replaced by scar was significantly smaller in our patients with unrecognized than in those with recognized infarction (7 versus 17%).

Severity and extent of coronary artery narrowing: The amount and extent of coronary narrowing by atherosclerotic plaque in the entire lengths of the 4 major epicardial coronary arteries were examined qualitatively and quantitatively in all 61 patients, and no significant difference between the 2 study groups was observed. The patients with unrecognized or recognized infarcts had a similar mean number of coronary arteries narrowed severely (76 to 100% in cross-sectional area) (2.9 versus 2.8 of 4.0), a similar incidence of severe narrowing of the left main coronary artery (29 versus 18%), a similar overall percent of severely narrowed 5 mm coronary segments (43 versus 42%), and a similar percent of severely narrowed 5 mm segments of the left anterior descending, left circumflex, and right coronary arteries. To our knowledge, this information on clinically unrecognized infarct patients is not available elsewhere.

In summary, our necropsy patients with clinically unrecognized compared with those with clinically recognized healed transmural infarcts had similar incidences of angina pectoris and fatal acute myocardial infarction and higher incidences of diabetes mellitus and noncardiac causes of death, smaller infarcts more often located in the posterior wall of left ventricle, and similarly severe and extensive coronary narrowing by atherosclerotic plaque.

Anatomic and Prognostic Implications of an Early Positive Treadmill Exercise Test

RICKY M. SCHNEIDER, MD, JOHN F. SEAWORTH, MD, MARY L. DOHRMANN, MD, ROBERT M. LESTER, MD, HARRY R. PHILLIPS, Jr., MD, THOMAS M. BASHORE, MD, and JOHN T. BAKER, MD

Eighty men (group A) with clinical coronary artery disease underwent coronary angiography regardless of symptoms and previous therapy because they had a positive treadmill exercise test in stage I or II of the Bruce protocol. Thirty-four other men (group B) who also had an early positive treadmill test underwent coronary angiography because they had disabling angina pectoris despite medical therapy. We found left main coronary artery stenosis of 50% or greater of the vessel diameter in 28% of group A and 35% of group B ($p > 0.3$). In contrast, only 10% of 93 other catheterized patients who had treadmill tests that were not early positive had left main coronary disease ($p < 0.001$). Fifty-four patients from group A who did not have left main stenosis of 50% or greater were treated medically. In this subgroup, 85% had 2 or 3 major coronary vessels with 75% or greater stenosis. These patients had a 36 month survival rate of 89.2%.

We conclude that an early positive treadmill test identifies patients who have an increased likelihood of having left main coronary stenosis, even if they are minimally symptomatic. To identify left main coronary stenosis, catheterization may be justified in patients whose angina pectoris has been mild or not intensively treated when they have an early positive treadmill response. After left main coronary stenosis has been excluded, these patients may be treated medically with a low mortality.

Aortocoronary bypass surgery improves survival in symptomatic patients with left main coronary artery disease.[1-8] For this reason, investigators have attempted to find noninvasive tests that will identify patients with significant narrowing of the left main coronary artery.[9] Retrospective studies of patients who underwent cardiac catheterization because of severe angina pectoris have found an association between an ischemic electrocardiographic response in the early stages of treadmill exercise testing and significant left main coronary stenosis.[10-15] This association would be important clinically if it could be confirmed prospectively in patients with mild angina pectoris who might not ordinarily be considered candidates for coronary angiography and aortocoronary bypass surgery.[16]

An ischemic electrocardiographic response at low levels of exercise has also been reported to identify a subgroup of patients who have a poor prognosis on medical therapy.[12,17-19] This has led some clinicians[20] to use the treadmill test result, even after the coronary anatomy and left ventricular function are defined, as an indication that aortocoronary bypass surgery should be performed. However, a recent study[21] found that patients who had marked S-T segment depression during treadmill exercise, even in its early stages, could be treated medically with a low mortality.

In the present study we performed cardiac catheterization in 80 patients who had an exercise test that was positive in stage I or II of the Bruce protocol but who did not have angina pectoris that was refractory to medical therapy. We compared this study group with a group of patients who had angina pectoris that was refractory to medical therapy and who also had stage I or II positive

treadmill tests. Our purpose was to determine (1) the predictive value of an early positive treadmill response for left main coronary stenosis in patients who were selected for cardiac catheterization because of an early positive treadmill response at a time when they were not already considered clinically to be candidates for aortocoronary bypass therapy, and (2) the prognosis on medical therapy of patients in this group who were found at catheterization not to have significant left main stenosis.

Methods

Study population: Between January 1977 and December 1978, 378 patients with a clinical diagnosis of coronary artery disease underwent 391 cardiac catheterizations. Of these patients, 358 had not previously undergone aortocoronary bypass surgery. Treadmill exercise tests were performed before catheterization in 207 patients. Exercise tests were not generally performed in patients with severe angina pectoris who were already being considered for aortocoronary bypass surgery because of an unsatisfactory response to medical treatment. One hundred fourteen patients had an early positive treadmill test, that is, an ischemic electrocardiographic response to treadmill exercise in stage I or stage II of the Bruce protocol. These 114 patients constitute the study population.

The study population was divided by prospective definition into 2 groups. Group A consisted of 80 men who were catheterized because their treadmill tests became positive in stage I (37 patients) or stage II (43 patients). None of these patients had angina pectoris that had been shown to be refractory to medical management. All of them had angina pectoris or electrocardiographic evidence of a previous myocardial infarction (0.04 second Q waves), or both. Before 1977 these patients would not have been considered candidates for cardiac catheterization at our institution because they had minimal symptoms or had not yet had an adequate trial of medical therapy. They were offered cardiac catheterization because previous data obtained in patients with medically refractory angina suggested that an early positive treadmill response predicts an increased risk of left main coronary stenosis.[12]

Group B consisted of 34 men who also had stage I (19 patients) or stage II (15 patients) positive treadmill tests, but who were catheterized because (1) they had severe angina pectoris, defined as New York Heart Association[22] functional class III or IV, and (2) they had received an adequate trial of medical therapy, defined as a combination of propranolol (more than 160 mg/day, unless there was documented intolerance to this dose) and long-acting nitrates. Until the first patients were recruited into this study in 1977, our primary indication for cardiac catheterization in coronary artery disease was disabling angina pectoris that had not responded to medical management. Group B, therefore, represented a group of patients who were selected for cardiac catheterization by criteria that were similar to those used in previous studies of exercise testing at this and other institutions.[12,16]

Treadmill exercise tests: Graded treadmill exercise tests were performed according to the Bruce protocol.[23] Exercise stages lasted 3 minutes. Treadmill exercise in stage I was performed at 1.7 miles/h and a 10% incline, with an estimated energy expenditure of 4 to 4.5 METS (multiples of resting oxygen consumption). Exercise in stage II was performed at 2.5 miles/h and a 12% incline, with an estimated energy expenditure of 7 METS. Exercise was submaximal and was terminated when criteria for a positive response were met or when the heart rate exceeded 85% of the maximum heart rate predicted for the patient's age, if exhaustion or severe symptoms did not occur first.

A positive response to exercise was defined as (1) J point depression of at least 0.1 mV below the P-R segment associated with a horizontal or downsloping S-T segment of 0.08 second duration (in the presence of 0.05 mV or greater J point depression in the control tracing, additional depression of at least 0.2 mV was required), or (2) S-T elevation of at least 0.1 mV above baseline. Precordial leads V_4, V_5, and V_6 were continuously monitored during exercise. A standard 12 lead electrocardiogram was performed at the end of each minute of exercise and repeated every 2 minutes after exercise was terminated for a minimum of 6 minutes or until changes had returned to baseline. Patients whose electrocardiograms became positive during the recovery period were considered positive at the stage in which they had terminated exercise.

Cardiac catheterization: Right and left heart catheterization was performed in all patients using the Judkins technique.[24] Hemodynamic measurements were routinely made before cineangiography. Cardiac output was calculated by the Fick method,[25] and left ventricular ejection fraction was determined by planimetry using the single plane right anterior oblique view.[26] Coronary angiograms were performed in multiple left anterior oblique and right anterior oblique projections. A stenosis that reduced the luminal diameter by 75% or more was considered significant, except in the left main coronary artery, where a stenosis of 50% or more was defined as significant.

Follow-up: Decisions regarding patient management after cardiac catheterization were made by referring physicians, who also provided subsequent medical care. Follow-up information for group A was obtained 6 months and annually after cardiac catheterization, and finally in September 1981, either by a staff cardiologist during a clinic visit or by a research associate by telephone. The follow-up was complete in all 80 patients. At each evaluation, if there was suspicion of myocardial infarction, hospital records were reviewed or personal physicians were contacted for corroborating electrocardiographic or enzymatic evidence. When a patient died, a description of the cause and circumstances was sought from the hospital record, the private physician, or a family member. Most patients in group B underwent aortocoronary bypass surgery; their follow-up data will not be presented.

Data analysis: Differences between patient groups in clinical, angiographic, and treadmill variables were evaluated

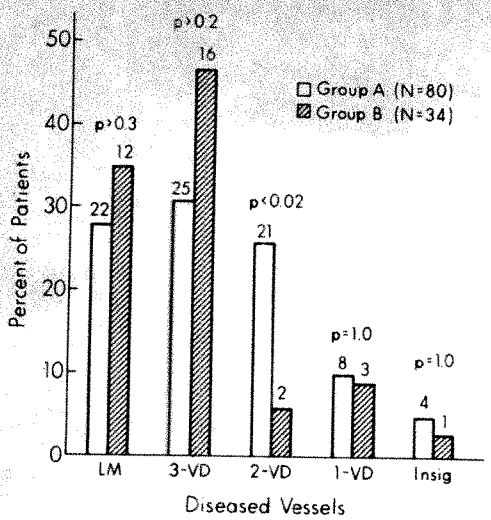

FIGURE 1. Coronary arteriographic findings in groups A and B. Absolute numbers of patients are **above the bars,** as are p values comparing group A and B patients. Insig = insignificant coronary disease; LM = left main coronary lesions of 50% or greater; excluding patients with left main stenosis of 50% or greater, 3-VD = 3 vessel disease, 2-VD = 2 vessel disease, and 1-VD = 1 vessel disease.

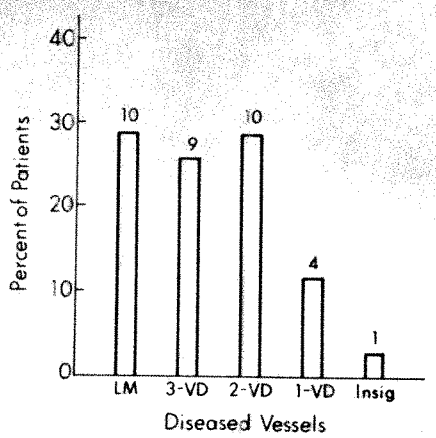

FIGURE 2. Coronary arteriographic findings in 34 group A patients with New York Heart Association angina pectoris class I and II. Absolute numbers of patients are **above the bars.** The percentages of patients did not differ from those in group A as a whole (p >0.3 for each anatomic category). Abbreviations as in Figure 1.

by contingency table analyses utilizing chi-square tests of significance or, when patient numbers were small, Fisher's exact test. Hemodynamic variables were examined between groups by a 1 way analysis of variance. Cumulative survival rates after cardiac catheterization were computed by the method of Kaplan and Meier.[27] Medically treated patients who subsequently underwent surgery were withdrawn from the medical group in the month of their operation.

Results

Study population (Table I): Groups A and B did not differ significantly in mean age or number of patients with a previous myocardial infarction. The distribution of functional classes for angina pectoris and the extent of antianginal therapy were substantially different in groups A and B as a result of the criteria used for patient enrollment (see Methods).

Cardiac catheterization findings (Fig. 1): Thirty-four of our 114 patients (30%) had significant left main coronary artery stenosis, including 22 patients (28%) in group A and 12 patients (35%) in group B (p >0.3). Twenty-two of these 34 patients (19% of our study population) had left main stenosis that reduced the luminal diameter by at least 75%, with 15 (19%) in group A and 7 (21%) in group B (p = 1.0).

Among our 80 patients without significant left main coronary stenosis, 25 patients (31%) in group A had 3 vessel disease, compared with 16 patients (47%) in group B (p >0.2). Group A had more 2 vessel disease than group B (26% versus 6%, p <0.02; this p value must be interpreted with caution because of the number of tests already performed on the study population). Similar percentages of patients in each group had 1 vessel disease and insignificant coronary disease.

In patients with significant coronary artery lesions, left ventricular end-diastolic pressure was 14.6 ± 6.6 (mean ± standard deviation) mm Hg in group A and 15.2 ± 6.8 in group B; the mean cardiac index was 2.71 ± 0.36 liters/min/m^2 in group A and 2.69 ± 0.43 in group B; and the mean ejection fraction was 60 ± 14% in group A and 59 ± 13 in group B. These differences were not statistically significant.

Coronary anatomy in functional class I and II patients (Fig. 2): Thirty-four patients in group A who were in class I (8 men) or class II (26 men) for angina pectoris at the time of their early positive treadmill tests and cardiac catheterization were examined separately. Ten patients (29%) had significant left main coronary stenosis; 7 (21%) had stenosis of 75% or greater of the vessel diameter.

Coronary anatomy in other exercised patients (Fig. 3): Ninety-three of the 207 patients who had treadmill test evaluation before cardiac catheterization had test results that were not positive early in exercise. Only 9 patients (10%) had significant left main coronary stenosis (p <0.001 compared with groups A and B combined); these included 1 of 21 patients who had a negative test, 4 of 50 patients who had an indeterminate test, and 4 of 22 patients who had a test that became positive in stage III or later. Only 6 patients (6%) had left main coronary stenosis of 75% or greater of the vessel diameter (p <0.01 compared with groups A and B combined). One vessel coronary disease and insignificant disease were found more frequently in the group of exercised patients whose tests were not early positive than in those in study groups A and B (Fig. 3).

Coronary anatomy predicted by treadmill test variables: In order to assign a predictive value to early positive treadmill tests, we divided the number of patients with early positive treadmill tests into the number of those same patients with left main coronary stenosis, 3 vessel disease, and either left main stenosis or 3 vessel disease; the resulting predictive values for group A patients were 28% for left main stenosis, 31% for 3 vessel

TABLE II Coronary Anatomy Predicted by Treadmill Variables*

Variable	n	Left Main (n = 22)	3-VD (n = 25)	Left Main or 3-VD (n = 47)
Onset of S-T changes				
Stage I	37	12 (32)	16 (43)	28 (76)
Stage II	43	10 (23)	9 (21)	19 (44)
Onset in recovery period	9	3 (33)	3 (33)	6 (67)
Maximum stage reached

Leads with S-T change				
≥3 leads	60	19 (32)	20 (33)	39 (65)
≥6 leads	20	6 (30)	7 (35)	13 (65)
HR ≤120 beats/min	34	10 (29)	13 (38)	23 (68)
Time until S-T recovery				
≥2 minutes	60	17 (28)	16 (27)§	33 (55)§
≥6 minutes	28	10 (36)	7 (25)	17 (61)

* Numbers in parentheses indicate predictive value (in percent) of each exercise variable for each anatomic description. No variable had a predictive value statistically greater than the stage I or II onset of S-T changes alone.
† Treadmill recordings unavailable for analysis in 1 patient.
‡ Several patients had both S-T elevation and S-T depression in different leads.
§ Treadmill recordings inadequate for analysis in 2 patients.
HR = heart rate; left main = significant left main coronary stenosis; 3-VD = 3 vessel disease (excluding left main patients).

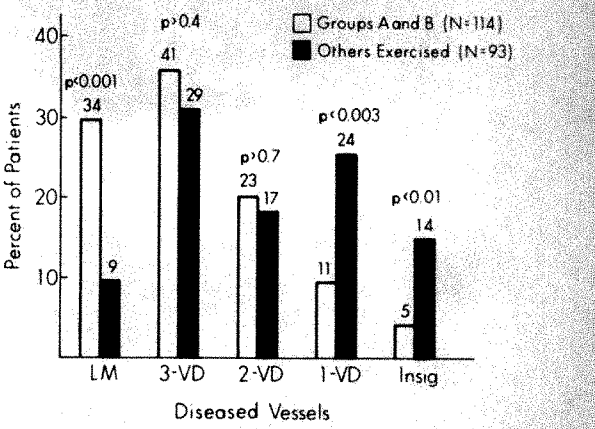

FIGURE 3. Coronary arteriographic findings in combined groups A and B compared with other exercised patients who did not have an early positive treadmill test. Absolute numbers of patients are **above the bars,** as are p values comparing the 2 populations. Abbreviations as in Figure 1.

disease, and 59% for left main or 3 vessel disease. We also determined the predictive values of 8 other treadmill variables in group A (Table II) and group B; none was a statistically significant improvement over the early positive treadmill test.

Follow-up data: We followed up the 54 patients from group A who had significant coronary disease that did not involve the left main coronary artery for up to 53 months (median 36 months). Forty-six patients (85%) had multivessel coronary artery disease, including 25 (46%) patients with 3 vessel and 21 (39%) with 2 vessel disease. Twelve patients (22%) had a left ventricular ejection fraction less than 50%.

All 54 patients were initially treated medically; 12 (22%) underwent aortocoronary bypass surgery 1 week to 40 months (median 12 months) after catheterization because of the development of disabling angina pectoris refractory to antianginal therapy. Seven of these patients had a second cardiac catheterization before surgery.

Five of the 42 patients who were medically treated for the duration of the study died, 4 from myocardial infarction 8, 17, 28, and 31 months after cardiac catheterization, and 1 from unknown cause 9 months after catheterization. There were no other episodes of myocardial infarction among medically treated patients. Kaplan-Meier estimates of survival probability were 98.0 ± 2.0% (± standard error of the estimate) at 8 months, 96.0 ± 2.8% at 9 months, 93.8 ± 3.5% at 17 months, 91.5 ± 4.1% at 28 months, and 89.2 ± 4.6% at 31 months (Fig. 4).

The 22 patients from group A who had significant left main coronary stenosis were followed up for up to 58 months (median 45 months). Fourteen patients (64%) underwent aortocoronary bypass surgery 1 week to 5 months (median 3 weeks) after catheterization. One patient died from unknown cause 2 months after surgery. One patient had a documented myocardial infarction 27 months after surgery. Thirteen patients who had surgery survived the follow-up period.

Eight patients with significant left main coronary stenosis were treated medically. One died from an acute myocardial infarction 33 months after catheterization. The remaining 7 patients survived the follow-up period.

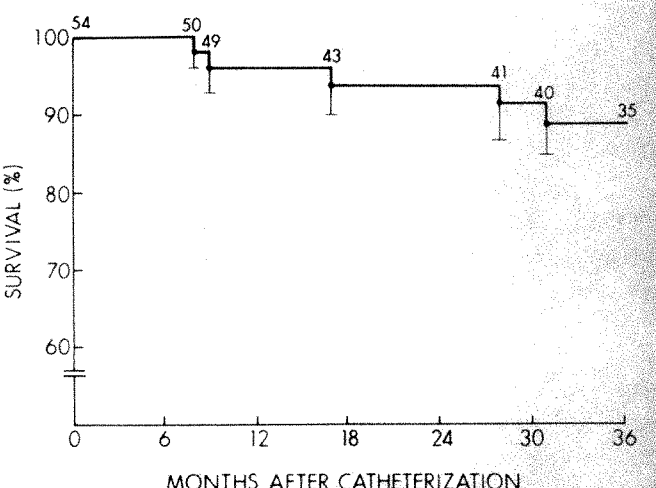

FIGURE 4. Kaplan-Meier estimates of probability of survival in patients with coronary artery disease catheterized because of an early positive treadmill test (group A), excluding patients with significant left main stenosis. Standard errors of the estimates are indicated. **Numbers above the graph** indicate patients at risk.

Discussion

Anatomic findings: The survival of patients with coronary artery disease depends on the extent and distribution of stenotic lesions and on the overall function of the left ventricle.[28–33] Significant stenosis of the left main coronary artery has a poor prognosis,[34–39] which may be substantially improved by aortocoronary bypass surgery.[1–8] Published series have reported significant left main stenosis in 2.6 to 9% of patients with coronary disease.[31,34,36,38,40] The patients in these series generally underwent cardiac catheterization because they were highly symptomatic. However, among 156 asymptomatic or mildly symptomatic patients with coronary artery disease who were evaluated at the National Institutes of Health,[41] a comparable 10% had significant left main stenosis.

Prediction of left main coronary disease by exercise testing: Several retrospective investigations[10–15] have shown that an ischemic electrocardiographic response to treadmill exercise can predict left main coronary stenosis in symptomatic patients. McNeer et al.[12] demonstrated that 27% of patients with a positive test who stopped treadmill exercise in stage I and 24% of those who stopped in stage II had significant left main stenosis. Weiner et al.[10] found that 0.2 mV or greater downsloping S-T depression beginning in stage I, lasting at least 6 minutes into the recovery period, and involving at least 5 electrocardiographic leads had a 32% predictive value for significant left main stenosis. We found a 35% predictive value for left main disease in our patients with medically refractory and disabling angina pectoris (group B) by relying simply on the onset of a positive S-T segment response in treadmill stage I or II.

In our prospective study, we found left main coronary disease in 28% of our patients catheterized because of an early positive treadmill test (group A), which confirms that patients with an ischemic electrocardiographic response at low levels of exercise have an increased likelihood of having left main disease. This conclusion appears equally valid in the subgroup of patients with class I or II angina pectoris, 29% of whom had left main disease. Similar results were reported by Epstein et al.,[41] who found that 32% of their asymptomatic or mildly symptomatic patients who had S-T depression of 0.2 mV or greater during treadmill exercise also had significant left main stenosis. Blumenthal et al.[42] found that 35% of patients with class I or II angina pectoris who met any 1 of 6 criteria for a "strongly positive" treadmill test had left main disease.

Recent data indicate that the poor outcome associated with medically treated left main coronary disease may be limited to patients whose lesions reduce the luminal diameter by more than 75%.[40,43] Left main stenosis meeting this criterion was present in 19% of all patients with an early positive treadmill test and in 21% of the subgroup of group A with class I or II angina pectoris.

We compared cardiac catheterization findings in groups A and B to determine whether substantial group differences in symptoms of angina pectoris would translate into differences in distribution of coronary disease and in ventricular function. Instead, we found that these 2 populations of patients had similar hemodynamic function and ejection fractions and similar incidences of significant left main and 3 vessel coronary artery disease.

Combining groups A and B results in a total of 114 patients who had early positive treadmill tests. Thirty % of these patients had significant left main stenosis, compared with only 10% of the 93 other exercised patients ($p < 0.001$, Fig. 3). This comparison indicates that in our catheterized population, an early positive exercise test selected patients who were 3 times more likely to have left main disease than were those whose treadmill tests were not positive early.

Many other variables of the treadmill test have been reported to be useful for identifying patients with an increased likelihood of having left main stenosis.[44–48] We attempted retrospectively to enhance the ability of the early positive treadmill test to predict significant left main or 3 vessel disease by individually analyzing other exercise variables, but we could identify no single variable that improved the predictive value of the early positive test. It is possible that combinations of variables might have resulted in a higher predictive value, or that individual variables might have enhanced the predictive value of the exercise test in a larger patient population.

Prognostic findings: Several studies[12,17–19] have demonstrated that ischemic electrocardiographic responses early in exercise indicate a poor prognosis. McNeer et al.[12] retrospectively found that a positive treadmill test in patients who were forced to stop exercise in stage I or II of the Bruce protocol identified a "high risk subgroup" with a 12 month cumulative survival rate of 85% and a 36 month survival rate of 69%. Follow-up of our 54 medically treated patients in group A without significant left main coronary stenosis revealed an estimated 12 month survival rate of 96.0% and a 36 month survival rate of 89.2%.

Important differences in these 2 patient populations may explain the disparity in survival. First, McNeer et al.[12] included medically treated patients with significant left main stenosis, while we excluded these patients. Second, the distribution of coronary anatomy and ventricular function may have been different. Third, the patients analyzed by McNeer et al. were catheterized because of severe symptoms but did not undergo aortocoronary bypass surgery. Some of these patients may have been rejected for surgery on the basis of clinical or anatomic factors with an adverse effect on survival.

Finally, the primary indications for cardiac catheterization were different in the 2 populations. Patients selected for angiographic evaluation because of disabling angina pectoris despite aggressive medical therapy may constitute a higher risk population than patients selected primarily on the basis of an early positive treadmill test. This clinical difference in the 2 populations may have important prognostic implica-

tions independent of the early positive exercise test and the anatomic severity of coronary artery disease and left ventricular dysfunction.

Some investigators have stated that in patients with known coronary anatomy, abnormal exercise responses provide important prognostic information[49] and indicate a need for aortocoronary bypass surgery.[20] However, recent investigations[29,50] suggest that exercise test variables may not contribute significantly to prediction of prognosis in coronary artery disease after multiple clinical and catheterization factors have been considered. A detailed analysis of 81 clinical and catheterization variables has shown that after a patient has been catheterized, the assessment of prognosis should be based on the coronary anatomy and ventricular function and not on treadmill test performance (Gibbons R, personal communication).

Podrid et al.[21] recently reported that 142 men with S-T segment depression greater than 0.2 mV during treadmill exercise had an annual mortality of 1.4%. A subgroup of 46 patients who exercised for 6 minutes or less had an annual mortality of 2.0%. Although these patients had clinical evidence of coronary artery disease, few had angiographic documentation of their disease. The authors of this study concluded that there is no need to resort to aortocoronary bypass surgery on the basis of a profoundly abnormal treadmill test alone.

Our study population differs from that of Podrid et al.[21] in that all patients had undergone elective cardiac catheterization. Our 36 month survival estimate of 89.2% yields an annual mortality of 3.6%. Taken together, the present investigation and the Podrid study suggest that medical management of patients with markedly abnormal treadmill exercise responses, even those with known severe coronary artery disease, is associated with a low mortality.

Dagenais et al.[51] found that among a catheterized and a noncatheterized population of patients who had S-T segment depression greater than 0.2 mV during treadmill testing, exercise duration identified subjects who had different survival rates. This issue cannot be addressed in the present study because the test protocol called for exercise to be terminated when criteria for a positive response were met or when the target heart rate was reached, unless exercise was first limited by symptoms.

This study is limited by the lack of a control population for group A to include patients who do not have early positive treadmill tests. We could not justify recommending cardiac catheterization to patients whose angina pectoris was mild or responsive to medical therapy, such as those in group A, when they did not have an early positive treadmill result. The 93 catheterized patients referred to in the Results section who had treadmill tests that were not positive early were identified retrospectively and are not an adequate control population. They were catheterized because of severe angina pectoris. They are included because they indicate the incidence of significant left main coronary disease (10%) in a population catheterized on the basis of severe symptoms.

Clinical implications: Our study confirms that a stage I or II positive treadmill test predicts an increased likelihood of significant left main coronary stenosis in patients with and without medically refractory, disabling angina pectoris. Furthermore, it indicates that an early positive exercise test has the same implication in patients who have mild angina pectoris or who are asymptomatic after myocardial infarction. These apparently stable patients have an increased incidence of presumably very threatening left main coronary disease, which justifies invasive evaluation.

In patients discovered to have left main stenosis, aortocoronary bypass surgery would be expected to improve prognosis. Once patients with early positive treadmill tests are demonstrated not to have significant left main disease, we believe they may be treated medically as long as their symptoms are adequately controlled by medication. These patients have had an excellent outcome over 3 years on conservative therapy, and functional impairment should continue to be the primary indication for surgical therapy in this group. An early positive treadmill result may not portend a high risk of mortality independent of the patient's functional status, the distribution of coronary disease, and the extent of ventricular dysfunction.

VISIT BOOTH L-6, AMERICAN HEART ASS'N IN DALLAS, NOV. 15–18

DOPPLER ULTRASOUND IN CARDIOLOGY:
Physical Principles and Clinical Applications
By LIV HATLE, M.D., *University of Trondheim, Department of Medicine, Trondheim, Norway; and* BJØRN ANGELSEN, dr. techn., *The Foundation of Scientific and Industrial Research at the Norwegian Institute of Technology, Trondheim, Norway.* The application of ultrasonic techniques for noninvasive diagnosis of the cardiovascular system has become increasingly popular. This unique book is the first in the field and presents new research and new means of using Doppler technique in cardiology, including physical principles. Eight chapters cover; physics of blood flow, principles of ultrasonic Doppler techniques, clinical application in cardiac diagnosis, aortic flow velocity and cardiac output, and a review of methods of spectral analysis useful for Doppler signal analysis. *238 pp., 175 illus., 1982, $27.00.*

CROSS-SECTIONAL ECHOCARDIOGRAPHY
By ARTHUR E. WEYMAN, M.D., *Harvard Medical School, Boston, Massachusetts.* This new book presents a comprehensive review of the historical development, physical principles, techniques and clinical applications of cross-sectional echocardiography. Although extensively illustrated, the reader is taken well beyond simple pattern recognition. A detailed and consistent method for cross-sectional image recording and interpretation is presented and an approach is developed whereby any user can produce accurate and reproducible data. Since it is primarily the work of a single author, the text is balanced, comprehensive, and free of redundancy. Because of its scope and gradual development, this book is an excellent text for the cardiologist, radiologist, echocardiographer in training and the technician in cardiology and radiology. *526 pp. (7 × 10), 401 illus., 1982, $48.50.*

CORONARY ARTERY DISEASE IN INFANTS AND CHILDREN
By HENRY N. NEUFELD, M.D. *and* ADAM SCHNEEWEISS, M.D., *both of Tel Aviv University Sackler School of Medicine, Tel-Hashomer, Israel.* Doctors Neufeld and Schneeweiss, both respected professionals in their field, have written a comprehensive treatise on all aspects of coronary artery disease in infants and children with which every clinician in the field should be familiar. Congenital coronary disease, nonatherosclerotic coronary disease, risk factors of coronary atherosclerosis in infancy and childhood, variations of coronary patterns in both children and adults, coronary arteries in congenital heart disease and systems disease, and Kawasaki disease are just some of the topics discussed. *About 225 pp. (7 × 10), 118 illus., tables, references, January 1983.*

CARDIAC RHYTHM DISTURBANCES:
A Step by Step Approach
By WILLIAM FOX, M.D., *University of Chicago School of Medicine, Chicago, Illinois; and* EMANUEL STEIN, M.D., *Eastern Virginia Medical School, Norfolk, Virginia.* This is a skillfully written "how to" book on the interpretation of electrocardiograms. In addition to being an excellent teaching tool, it also serves as an atlas illustrating the vast majority of rhythm disturbances encountered in clinical practice. The authors have incorporated just the right amount of cardiac electrophysiology in the book. The book has been designed in such a way that it can accommodate readers with varying degrees of sophistication. The ECG and section sequences are organized so that one continually builds on knowledge acquired earlier on in the book. *About 250 pp. (8½ × 11), 241 ECGs (many with more than one tracing), 13 figures, 18 tables, January 1983.*

PROGRESS IN CARDIOLOGY.10
Edited by PAUL N. YU, M.D., *University of Rochester School of Medicine and Dentistry, Rochester, New York; and* JOHN F. GOODWIN, M.D., *Royal Postgraduate Medical School, London, England.* This tenth anniversary volume of PROGRESS IN CARDIOLOGY is very special. Dedicated to Sir John McMichael, it contains more pages than preceding volumes and both an author and subject index for all ten volumes. The authors, an international group of authorities and each an expert in his own area, have been asked to extrapolate on the future course of cardiovascular disease and treatment based on their own developing trends and evolution in research. Topics such as future trends in academic cardiology, prevention of coronary heart disease, congenital heart disease, electrophysiology, echocardiography, angiography, and nuclear cardiography are discussed. *409 pp. (7 × 10), illus., 1981, $38.50.*

FUNDAMENTAL CARDIOVASCULAR AND PULMONARY PHYSIOLOGY:
An Integrated Approach for Medicine
By JERRY FRANKLIN GREEN, Ph.D., *University of California School of Medicine, Davis.* This complete text is the only book which offers a complete and well-balanced review of both cardiovascular and pulmonary physiology under one cover. Basic concepts of volume-pressure and pressure-flow relationships as well as transport processes are discussed. A separate section is devoted to each of three topics: cardiac, vascular, and pulmonary physiology. This book is a fundamental overview for students of medicine, physiology, and the allied health sciences. Cardiologists, pulmonary specialists, anesthesiologists, surgeons, and inhalation therapists will appreciate the book's clinical style. *347 pp., 141 illus., tables, 1982, $20.00.*

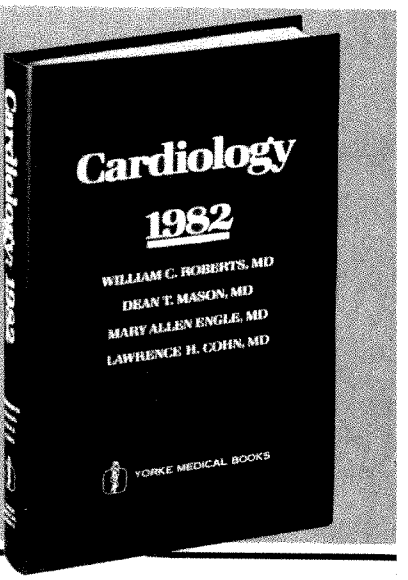
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES**, please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, New York 11205 AJCJ2

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)

The first and only
angiotensin
converting enzyme
(ACE) inhibitor
CAPOTEN®
(captopril tablets)
As a result of
ongoing clinical
studies, an
important new
indication for
CAPOTEN
is forthcoming.
SQUIBB
Innovators in
Cardiovascular
Medicine
Please see adjacent page for brief summary.

DESCRIPTION: Capoten (captopril) is a specific competitive inhibitor of angiotensin I-converting enzyme (ACE), the enzyme responsible for converting angiotensin I to angiotensin II.

INDICATIONS: Because serious adverse effects have been reported (see WARNINGS), Capoten is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects. Usually, multidrug regimens include combinations of a diuretic, a sympathetic nervous system-active agent (such as a beta-blocker) and a vasodilator.

Capoten (captopril) is effective alone, but in the population described above, it should usually be used in combination with a thiazide-type diuretic. The blood pressure lowering effects of captopril and thiazides appear to be additive.

WARNINGS: Proteinuria—Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. Existence of prior renal disease increased the likelihood of development of proteinuria. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued, but some patients had persistent proteinuria. The BUN and creatinine were seldom altered in the proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related; this is uncertain since patients were not biopsied prior to treatment and membranous glomerulopathy may be associated with hypertension in absence of captopril therapy. Since most cases of proteinuria occurred by the 8th month of captopril therapy, patients on captopril should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine—the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis—Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller, and it is sufficient in these patients to have white blood cell counts every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension—Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in severely salt/volume depleted persons such as those treated vigorously with diuretics, e.g., patients with severe congestive heart failure (see PRECAUTIONS [Drug Interactions]).

PRECAUTIONS: General: *Impaired Renal Function*—Some patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine after reduction of blood pressure with captopril. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible (see DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]). *Surgery/Anesthesia*—During major surgery or anesthesia with agents that produce hypotension, captopril will block angiotensin II formation secondary to compensatory renin release; if hypotension occurs and is considered due to this mechanism, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy*—A precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretic therapy and those on severe dietary salt restriction or dialysis. The possibility of hypotensive effects can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose. If hypotension occurs, place the patient in a supine position and, if necessary, administer an I.V. infusion of normal saline. This transient hypotensive response is not a contraindication to further doses which can be given without difficulty once the blood pressure has increased after volume expansion.

Agents Causing Renin Release—Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity—The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium—Since captopril decreases aldosterone production, elevation of serum potassium may occur. Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. If the patient has received spironolactone at any time up to several months prior to captopril therapy, determine the serum potassium frequently since the effect of spironolactone persists.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential.

Animal Toxicology: Chronic oral toxicity studies were conducted in rats (2 years), dogs (47 weeks; 1 year), mice (2 years), and monkeys (1 year). Significant drug-related toxicity included effects on hematopoiesis, renal toxicity, erosion/ulceration of the stomach, and variation of retinal blood vessels. Reductions in hemoglobin and/or hematocrit values were seen in mice, rats, and monkeys at doses 50 to 150 times the maximum recommended human dose (MRHD). Anemia, leukopenia, thrombocytopenia, and bone marrow suppression occurred in dogs at doses 8 to 30 times MRHD. The reductions in hemoglobin and hematocrit values in rats and mice were only significant at 1 year and returned to normal with continued dosing by the end of the study. Marked anemia was seen at all dose levels (8 to 30 times MRHD) in dogs, whereas moderate to marked leukopenia was noted only at 15 and 30 times MRHD and thrombocytopenia at 30 times MRHD. The anemia could be reversed upon discontinuation of dosing. Bone marrow suppression occurred to a varying degree, being associated only with dogs that died or were sacrificed moribund. Bone marrow suppression was found to be reversible upon continued drug administration. Captopril caused hyperplasia of the juxtaglomerular apparatus of kidneys at doses 7 to 200 times the MRHD in rats and mice, at 20 to 60 times MRHD in monkeys, and at 30 times the MRHD in dogs. Gastric erosions/ulcerations were increased in incidence at 20 and 200 times MRHD in male rats and at 30 and 65 times MRHD in dogs and monkeys, respectively. Rabbits developed gastric and intestinal ulcers when given oral doses about 30 times MRHD for only 5 to 7 days. In the two-year rat study, reversible and progressive variations in the caliber of retinal vessels (focal saccular dilations and constrictions) occurred at all dose levels (7 to 200 times MRHD) in a dose-related fashion. The effect was first observed in the 88th week of dosing, with a progressive increased incidence thereafter, even after cessation of dosing.

Pregnancy: Category C—Captopril was embryocidal in rabbits when given in doses 2 to 400 times (on a mg/kg basis) the maximum recommended human dose. The marked embryocidal effect in rabbits was most probably due to the particularly marked decrease in blood pressure caused by the drug in this species. Captopril given to pregnant rats at 400 times the recommended human dose continuously during gestation and lactation reduced neonatal survival. No teratogenic effects (malformations) have been seen in large doses of captopril in hamsters, rats, and rabbits.

There are no adequate and well-controlled studies in pregnant women. Captopril should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Concentrations of captopril in human milk are about 1% of those in maternal blood. The effect of low levels of captopril on the nursing infant has not been determined. Exercise caution when administering captopril to a nursing woman, and in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age with secondary hypertension and varying degrees of renal insufficiency. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal—One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients, but relationship to drug use is uncertain.

Hematologic—Neutropenia/agranulocytosis (probably drug related) occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic—Rash (usually maculopapular, rarely urticarial), often with pruritus, sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the first 4 weeks of therapy. The rash is usually mild and disappears within a few days of dose reduction, short-term treatment with an antihistaminic agent, and/or discontinuing therapy; remission may occur even if captopril is continued. Pruritus, without rash, in about 2 of 100 patients. Between 7 and 10% of patients with skin rash have shown an eosinophilia and/or positive ANA titers. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients—reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular—Hypotension in about 2 of 100 patients. See PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia—About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Weight loss may be associated with the loss of taste. Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although causal relationship has been established. A single case of hepatocellular injury with secondary cholestasis has been reported in association with captopril use. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renal vascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. Dosage must be individualized.

Give consideration to recent antihypertensive drug therapy, extent of blood pressure elevation, salt restriction, and other circumstances before initiating therapy. If possible, discontinue the patient's previous antihypertensive drug regimen for one week before starting captopril. Initial dose of CAPOTEN (captopril) is 25 mg t.i.d. If satisfactory blood pressure reduction is not achieved after 1 or 2 weeks, dose may be increased to 50 mg t.i.d. If the blood pressure has not been satisfactorily controlled after another 1 to 2 weeks, add a modest dose of a thiazide-type diuretic (e.g., hydrochlorothiazide, 25 mg daily). The diuretic dose may be increased at 1- to 2-week intervals until its highest usual antihypertensive dose is reached. If further blood pressure reduction is required, CAPOTEN (captopril) may be increased to 100 mg t.i.d. and then, if necessary, to 150 mg t.i.d. (while continuing the diuretic). The usual dose range is 25 to 150 mg t.i.d. A maximum daily dose of 450 mg CAPOTEN (captopril) should not be exceeded.

For patients with accelerated or malignant hypertension, when temporary discontinuation of current antihypertensive therapy is not practical, or when prompt titration to more normotensive blood pressure levels is indicated, current antihypertensive medication may be stopped and CAPOTEN (captopril) dosage promptly initiated at 25 mg t.i.d., under close medical supervision. The daily dose of CAPOTEN (captopril) may be increased every 2 hours until a satisfactory blood pressure response is obtained or the maximum captopril dose is reached. In this regimen, addition of a more potent diuretic, e.g., furosemide, may also be indicated. Beta-blockers may also be used in conjunction with captopril therapy (see PRECAUTIONS [Drug Interactions]), but the effects of the 2 drugs are less than additive.

Dosage Adjustment in Renal Impairment—Because CAPOTEN (captopril) is excreted primarily by the kidneys, excretion rates are reduced in patients with impaired renal function. These patients will take longer to reach steady-state captopril levels and will reach higher steady-state captopril levels for a given daily dose than patients with normal renal function. Therefore, these patients may respond to smaller or less frequent doses. Accordingly, for patients with significant renal impairment, initial daily dosage of CAPOTEN (captopril) should be reduced, and smaller increments utilized for titration, which should be quite slow (1- to 2-week intervals). After desired therapeutic effect has been achieved, dose should be slowly back-titrated to determine minimal effective dose. When concomitant diuretic therapy is required, a loop diuretic (e.g., furosemide), rather than a thiazide diuretic, is preferred in patients with severe renal impairment.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

Issued: July 1982

When patients need more potassium than tablets can easily offer...

©1982 Sandoz, Inc.

Consider the simplicity of KLORVESS® EFFERVESCENT GRANULES

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

The patient on higher doses of antihypertensive medication, diuretics and/or digitalis, may need additional potassium supplementation... 40 mEq/day or more. KLORVESS Effervescent Granules offer the following advantages:

- ***Each packet delivers 20 mEq of potassium***... compared with slow-release tablets that contain 10 mEq or less.
- ***Sparkling citrus flavor offers a high degree of patient compliance.*** Patients may even use KLORVESS as a "chaser" for other medications. Granules mix easily with cold water... no need for expensive juices to make palatable.
- ***Convenient effervescent granules dissolve almost immediately***... no waiting.
- ***Sugar-free, sodium-free, carbohydrate-free, dye-free formulation***... ideal for hypertensive, diabetic, or overweight patients.

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

A letter on the importance of building a medically aware public

Pfizer

PHARMACEUTICALS

PFIZER INC., 235 E. 42ND ST., NEW YORK, N.Y. 10017

Dear Doctor:

Scientific progress continues to result in significant new therapeutic advances. As you know, the positive results achieved with these treatments depend in good measure upon effective physician/patient communication. At the same time, there is a growing interest by the general public in becoming better informed on healthcare issues and in assuming a larger role in maintaining their own health. We believe that an informed patient has a better chance of being a healthier patient.

In an effort to help bring needed information to the public, Pfizer is embarking on a health education campaign. This campaign consists of a series of health information messages which will reach patients through newspapers, magazines and radio. In these messages, patients are informed of the symptoms of diseases such as hypertension and angina and are advised to seek the advice of their physicians in response to these symptoms. Moreover, the messages stress the need for periodic medical examinations to uncover asymptomatic conditions. A sample message in this series appears on the page opposite this letter.

This campaign is one part of a broad new Pfizer communications program. Another aspect of this effort is our Patient Information Program, which consists of providing comprehensive patient information books, such as Learning to Live with Angina, to physicians for distribution to their patients.

I take pride in this program and invite your participation and response.

Sincerely,

Sheldon G. Gilgore

Sheldon G. Gilgore, M.D.
President

...and how Pfizer is helping to make it happen

THE PFIZER HEALTHCARE SERIES

Do you know anyone who can pump 2,000 gallons of blood through 70,000 miles of blood vessels every day?

We do. It's you.

Every day, of every year, of your whole life, your heart is pumping 2,000 gallons of blood a day through 70,000 miles of blood vessels. And your heart usually does it without fuss or complaint.

A time comes when the job gets tough, as after age 35 or when burdens (like overweight) are added or when vessels that feed the heart muscle lose their ability to bring enough blood to meet oxygen and nutrition needs and remove wastes. Your heart's signal is a condition called angina pectoris.

The symptoms of angina can be any one or more of these:

A sense of tightness or heaviness in your chest
A pain in your shoulder or neck
A sense of fullness, a feeling of "indigestion"

These symptoms are different for different people and at different times in any one person. The important thing is to pay attention, your body is telling you something is wrong. Your heart is giving you a signal to act promptly. See your doctor because angina must and can be treated.

The diagnosis of angina pectoris can be made only by your doctor.

The treatment of angina depends upon a doctor's diagnosis and on the type of angina pectoris you may have. Is it the kind that's caused by spasm? Or thickening of coronary vessels that feed the heart? Or by both?

What's to be done?
Your doctor can help you reduce your cardiac workload by reducing weight, cholesterol, tension and stress. And he has a full range of medications that can relieve coronary spasm, improve the flow of blood to the heart and normalize heart rhythms. You can also help yourself with proper rest and relaxation, time for pleasure and recuperation and a program of moderate exercise.

If your condition is accompanied by elevated blood pressure, your doctor has other medicines that can bring it within normal range. In certain instances, surgery may be called for. Obviously you can't be your own doctor. You need a support system. We call it...

Partners in Healthcare

You are the most important partner.
Only you can spot the warning signs and report them to your physician. And it's you who must decide to accept the guidance and counseling of your physician and pharmacist. When medicines are prescribed, only you can take them as directed.

Your doctor interprets the warning signs, orders your tests, and makes the diagnosis.
Your physician also prescribes the best medication for you among those available—considering each drug's characteristics—and monitors your progress.

All those who discover, develop and distribute medicines complete the partnership.
Pfizer's ongoing research brings you essential medicines for a wide range of diseases, including angina pectoris. Through our development of these and many other medications, we are fulfilling our responsibility as one of your partners in healthcare.

Laragh's eagerly awaited new guide to understanding, diagnosing, and treating Hypertension *in its many forms...*

TOPICS IN HYPERTENSION

Edited by JOHN H. LARAGH, MD

Master Professor of Medicine, Chief, Cardiology Division
Director, The Cardiovascular Center
The New York Hospital-Cornell Medical Center

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice . . . and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions by 85 eminent specialists. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

The book is conveniently organized for effective consultation and reading.

Check the helpful contents...

SECTION 1
Some Biochemical and Pathophysiologic Aspects
1 The Biochemistry of the Renin-Angiotensin System and Its Role in Hypertension **2** Conversion of Angiotensin I to Angiotensin II **3** Angiotensin Receptors in Vascular Tissue **4** Vascular Angiotensin Receptors and Their Role in Blood Pressure Control **5** Renal Prostaglandins and the Regulation of Blood Pressure Renin Release and Sodium and Water Homeostasis **6** Linking the Kallikrein and Renin Systems via Activation of Inactive Renin: New Data and a Hypothesis **7** Control of Renin Release: Experimental Evidence and Clinical Implications **8** Blood Rheology in Hypertension and Cardiovascular Diseases **9** Renal Circulation in Hypertensive Disease **10** The Concept of Autoregulation of Total Blood Flow and Its Role in Hypertension **11** A Proposed Cybernetic System for Sodium and Potassium Homeostasis: Coordination of Aldosterone and Intrarenal Physical Factors
SECTION 2
Newer Physiologic Approaches to Diagnosis
12 Renin-Sodium Profiling: Why, How and When in Clinical Practice **13** How to Do a Plasma Renin Assay **14** The Renin Axis and Vasoconstriction Volume Analysis for Understanding and Treating Renovascular and Renal Hypertension **15** Clinical and Laboratory Diagnosis of Adrenocortical Hypertension
SECTION 3
Clinical and Prognostic Aspects
16 High Blood Pressure in Children: Problems and Guidelines for Evaluation and Treatment **17** Systolic Hypertension: Nonhomogeneous Diseases **18** Hypertension Associated with Early Stage Kidney Disease **19** Elevation of Serum Lipid Levels During Diuretic Therapy of Hypertension **20** Renin and Aldosterone Secretion in Pheochromocytoma: Effect of Chronic Alpha Adrenergic Receptor Blockade **21** Pathogenesis of Hypertension in Cushing's Syndrome: Glucocorticoid Excess **22** The Renin-Sodium Profile as a Predictor of Hypertensive Complications **23** The Hypertensive Diseases
SECTION 4
Modes of Therapy
PART I ***Beta Blockade***
24 Acute and Long-term Studies of the Mechanisms of Action of Beta Blocking Drugs in Lowering Blood Pressure **25** The Role of Beta Adrenoreceptor Blockade in Hypertension **26** Rapid Identification of Patients with Essential Hypertension Sensitive to Beta Blockade **27** The Predictive Value of Renin Profiling in the Choice of Treatment in Primary Hypertension, with Special Reference to Patients with Low Renin Values **28** Prazosin: An Alpha Adrenergic Blocking Agent in Treatment of Hypertension **29** Antihypertensive Effectiveness of Propranolol: Role of the Renin-Aldosterone Axis **30** Antihypertensive Beta Blocking Action as Related to Renin and Age: A Pharmacologic Tool to Identify Pathogenetic Mechanisms in Essential Hypertension **31** Modern System for Treating High Blood Pressure Based on Renin Profiling and Vasoconstriction-Volume Analysis: A Primary Role for Beta Blocking Drugs such as Propranolol
PART II ***Saralasin***
32 Usefulness and Limitations of Saralasin, a Partial Competitive Agonist of Angiotensin II, for Evaluating the Renin and Sodium Factors in Hypertensive Patients **33** AngiotensinBlockade:Its ClinicalSignificance
PART III ***Converting Enzyme Blockade: Basic and Clinical Aspects***
34 The Renin System in High Blood Pressure: Converting Enzyme Blockade for Analysis and Treatment **35** Estimating Renin Participation in Hypertension: Superiority of Converting Enzyme Inhibitor over Saralasin **36** Clinical Experience with Blockade of the Renin-Angiotensin-Aldosterone System by an Oral Converting Enzyme Inhibitor (Captopril) in Hypertensive Patients

Because slow-release KCl tablets are not for every patient...

the quick-release KCl tablet

Accuracy of a tablet—delivers all of the dose all of the time

Potassium *plus* chloride—the preferred salt

Once- or twice-a-day effervescent tablets

Safety of a liquid throughout the GI tract

No measuring or diluting needed

Choice of citrus or fruit-punch flavors

K-LYTE/CL®

Each effervescent tablet in solution supplies 25 mEq potassium chloride

It's everything you need in a potassium supplement.

Mead Johnson PHARMACEUTICAL DIVISION

Double-strength K-Lyte/Cl® 50 also available. Each effervescent tablet in solution supplies 50 mEq potassium chloride.

© 1982 Mead Johnson & Company • Evansville, Indiana 47721 USA

Please see following page for summary of prescribing information.

K-Lyte/Cl® 50 (Each effervescent tablet in solution supplies 50 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)
K-Lyte/Cl® (Each effervescent tablet in solution supplies 25 mEq potassium and chloride as supplied by potassium bicarbonate and L-lysine monohydrochloride.)

Description: K-Lyte/Cl 50 and K-Lyte/Cl are oral potassium and chloride supplements. Each K-Lyte/Cl 50 mEq tablet in solution provides 50 mEq of potassium and chloride as supplied by 2.24 gm of potassium chloride, 2.0 gm of potassium bicarbonate, and 3.65 gm of L-lysine monohydrochloride with 1.0 gm of citric acid, saccharin, natural and artificial flavor and artificial color. Each K-Lyte/Cl tablet in solution provides 25 mEq of potassium and chloride as supplied by 1.5 gm of potassium chloride, 0.5 gm of potassium bicarbonate and 0.91 gm of L-lysine monohydrochloride with 0.55 gm of citric acid, saccharin, natural and artificial flavor and artificial color.

Indications and Usage: All K-Lyte® products are used for therapy or prophylaxis of potassium deficiency. They are useful when thiazide diuretics, corticosteroids, or diarrhea cause excessive potassium loss: and when dietary potassium is low. These products may also be useful when potassium therapy is indicated in digitalis intoxication. K-Lyte/Cl 50 and K-Lyte/Cl are recommended in the management of hypokalemia accompanied by metabolic alkalosis and hypochloremia, e.g., as induced by vomiting.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions; chronic renal impairment, metabolic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns or adrenal insufficiency. Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Warnings: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and may be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Precautions: *General precautions* – The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. When interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Therefore, the treatment of potassium depletion requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the ECG, and the clinical status of the patient.
Information for patients – To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, patients should be carefully directed to dissolve each dose completely in the stated amount of water.
Laboratory tests – Frequent clinical evaluation of the patient should include ECG and serum potassium determinations.
Drug interactions – The simultaneous administration of potassium supplements and a potassium-sparing diuretic can produce severe hyperkalemia (see Contraindications). Potassium supplements should be used cautiously in patients who are using salt substitutes because most of the latter contain substantial amounts of potassium. Such concomitant use could result in hyperkalemia.
Usage in pregnancy – Pregnancy Category C – Animal reproduction studies have not been conducted with any of the K-Lyte products. It is also not known whether these products can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. They should be given to a pregnant woman only if clearly needed.
Nursing mothers – Many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from oral potassium supplements, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.
Usage in children – Safety and effectiveness in children have not been established.

Adverse Reactions: The most common adverse reactions to oral potassium supplements are nausea, vomiting, diarrhea and abdominal discomfort. These side effects occur most frequently when the medication is not taken with food or is not diluted properly or dissolved completely.
Hyperkalemia occurs only rarely in patients with normal renal function receiving potassium supplements orally. Signs and symptoms of hyperkalemia are cardiac arrhythmias, mental confusion, unexplained anxiety, numbness or tingling in hands, feet or lips, shortness of breath or difficult breathing, unusual tiredness or weakness and weakness or heaviness of legs (see Contraindications, Warnings and Overdosage).

Dosage and Administration: *Adults* – One (1) K-Lyte/Cl 50 tablet (50 mEq potassium and chloride) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily, depending on the requirements of the patient. One (1) K-Lyte/Cl tablet (25 mEq potassium and chloride) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily, depending on the requirements of the patient.
Note: It is suggested that all K-Lyte products be taken with meals and sipped slowly over a 5 to 10 minute period.

How Supplied: K-Lyte/Cl® Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30, 100 and 250. K-Lyte®/Cl 50 Effervescent Tablets (citrus or fruit punch flavors) are available in cartons of 30 and 100. Each tablet is individually foil wrapped.

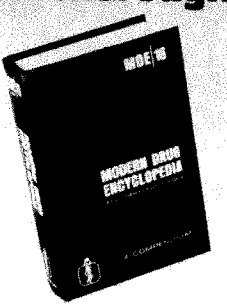
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

Effect of Nifedipine on Exercise-Induced Left Ventricular Dysfunction and Myocardial Hypoperfusion in Stable Angina

NADIM M. ZACCA, MD, MARIO S. VERANI, MD, ROBERT A. CHAHINE, MD, and RICHARD R. MILLER, MD

To assess the effects of nifedipine on left ventricular function and regional myocardial perfusion, exercise radionuclide ventriculography was performed in 15 men (median age 59 years) and exercise thallium-201 scintigraphy was done in 11 of them, before and 90 minutes after the oral administration of 20 mg of nifedipine. All patients had stable angina and angiographically proved coronary artery disease without evidence of spasm. Exercise tolerance after administration of nifedipine increased from 343 ± 42 seconds to 471 ± 50 seconds ($p < 0.01$), whereas the peak exercise double product remained essentially unchanged (difference not significant). Ejection fraction improved significantly at rest (from 49 ± 3.6% to 52 ± 3.3%, $p < 0.05$) and at peak exercise (42 ± 3.3% to 47 ± 3.7%, $p < 0.05$). Nifedipine also resulted in an improved segmental wall motion score (4.3 ± 2.3 to 3.0 ± 2.3, $p < 0.05$; 0 = normal and 4 = worst degree of dysfunction). The ejection fraction increased by more than 5% in one third of the patients at rest, and in more than half of the patients at peak exercise. Improved exercise myocardial perfusion occurred in 5 of 11 patients (45%) and in 7 of 28 segments (25%) with reversible hypoperfusion. Thus, nifedipine produces significant improvement in global and regional left ventricular function in patients with coronary artery disease and stable angina. This may be accounted for, at least in part, by improvement in myocardial perfusion.

Nifedipine is a calcium antagonist with potent vasodilating properties.[1–4] It has been used successfully in the treatment of stable angina pectoris and other ischemic syndromes[5–10] and has also been noted to have a negative inotropic effect in the isolated cardiac muscle preparation.[11] However, reports on its effects on myocardial function in patients with cardiac disease have been conflicting.[12–14] In particular, its possible influence on the acute left ventricular dysfunction resulting from stress-induced ischemia has not been sufficiently investigated. The present study was designed to assess the effects of nifedipine on left ventricular function at rest and during exercise in patients with coronary artery disease and stable angina pectoris. Myocardial perfusion scintigraphy was also performed in an attempt to elucidate the mechanism underlying such effects in these patients.

From the Section of Cardiology, Department of Medicine, Baylor College of Medicine and the Veterans Administration Medical Center, Houston, Texas. Manuscript received May 8, 1982; revised manuscript received May 17, 1982, accepted May 25, 1982.

Address for reprints: Nadim M. Zacca, MD, Cardiac Catheterization Laboratories (111B), 2002 Holcombe Boulevard, Houston, Texas 77211.

Material and Methods

Study patients: Fifteen men ranging in age from 47 to 70 years (median 59) were studied. All subjects gave a history of chronic stable angina pectoris and were taking nitrates and beta blocking agents, or both, which were withheld for at least 72 hours before this investigation. No patient had a myocardial infarction within at least 3 months before the trial. No patient had a history of variant angina and S-T segment elevation, or both, during chest pain. Written informed consent was obtained in each case before the administration of nifedipine.

All patients had undergone cardiac catheterization and coronary angiography within the previous 12 months. Critical coronary disease (greater than 70% reduction of luminal diameter) in at least 1 major coronary artery was present in all patients. Ten patients had triple vessel involvement, and 3 had double vessel and 2 single vessel disease (Table I). Neither spontaneous nor catheter-induced spasm was seen during

angiography. Because of the severity of the coronary lesions, spasm provocation was not attempted. Cardiac scintigraphic studies were performed in the postabsorptive state according to the following protocol: 1st day, exercise thallium-201 scintigraphy before nifedipine; 2nd day, resting and supine bicycle exercise gated radionuclide ventriculography before and 90 minutes after 20 mg of nifedipine taken orally; and 5th day, exercise thallium-201 scintigraphy 90 minutes after administration of oral nifedipine. The postnifedipine studies were performed 90 minutes after the administration of the drug because human pharmacokinetic investigations have shown that nifedipine reaches a peak concentration in the serum 1 to 2 hours after its oral administration.[15]

A 12 lead electrocardiogram at rest was obtained in each patient before the study. Exercise was performed in the supine position on a calibrated Quinton bicycle ergometer mounted on a radionuclide imaging table. Exercise was initiated at a work load of 200 kg/min and increased by 100 kg/min every 3 minutes. The patients were instructed to pedal at a speed of 50 to 60 rpm. Twelve lead electrocardiograms were recorded at 3 minute intervals just before increasing the work load. Three precordial leads were monitored continuously. Arterial blood pressure was measured with a cuff sphygmomanometer at 1 minute intervals during the study. The patients were exercised to symptomatic end points: moderately severe chest pain, shortness of breath, leg fatigue, or exhaustion. The same exercise protocol was used for the radionuclide angiograms before and after nifedipine. For the perfusion scintigrams, thallium-201 was injected at similar heart rate-blood pressure product before and after administration of nifedipine.

Ex = exercise; N = nifedipine.

The severity of exercise-induced angina was scored as follows: 2+ = moderate or intensity similar to the patient's usual episodes; 3+ = severe or intensity greater than the patient's usual episodes; and 1+ = mild or intensity lesser than usual episodes. A group score before and after administration of nifedipine was obtained by averaging the individual scores. Ischemic S-T shifts on the exercise ECG were considered present when 1 mm or greater horizontal or downsloping S-T segment depression occurred for at least 0.08 second past the J point.

Radionuclide angiography: An in vivo red blood cell labeling technique was used.[16] For this purpose, 7.5 mg of stannous pyrophosphate (Pyrolite, New England Nuclear, North Billerica, Massachusetts) was injected intravenously, followed 30 minutes later by 20 mCi of technetium-99m pertechnetate. Imaging was performed at rest in the anterior projection and in the left anterior oblique (LAO) projection, which allowed best delineation of the interventricular septum (usually 40 to 45° LAO). Exercise studies were performed only in the LAO projection. An all-purpose parallel hole collimator was utilized. Images were collected and processed using a gamma scintillation camera interfaced with an on-line dedicated computer (Ohio Nuclear 420-550 system). Multigated equilibrium blood pool imaging was performed during a preset time for 3 minutes at rest and for each work load. The cardiac cycle was divided into 16 frames allowing a minimum of 200,000 counts/frame to be obtained. The left ventricular ejection fraction was calculated using a computer program following Burow's technique.[17] A normal ejection fraction response to exercise is defined as a 5% increase from rest to peak exercise and an absolute value equal to or greater than 50%.[17]

Left ventricular wall motion was assessed qualitatively and independently by 3 experienced observers as described previously.[18] Briefly, the ventricle was divided into anterolateral, apical, and inferior walls on the anterior view; and septal, inferoapical, and posterolateral walls on the LAO view. Regional wall motion was assessed using a 5 point score system: 0 = normal, 1 = mild hypokinesia, 2 = moderate hypokinesia, 3 = severe hypokinesia, and 4 = akinesia or dyskinesia. A regional wall motion index was thus obtained by averaging the individual scores of all observers for each patient.

Exercise thallium-201 imaging: Eleven patients were evaluated with exercise thallium-201 scintigrams before and after nifedipine. The exercise protocol was similar to the radionuclide angiography protocol. Approximately 60 seconds before the termination of exercise, 1.5 mCi of thallium-201 was injected intravenously. Immediately after the completion of exercise and 4 hours later, imaging was performed with the patient supine in the anterior, 45°, and 70° LAO projections, using the same imaging system (Ohio Nuclear 420-550 system). A total of 400,000 counts were collected for each image.

Scintigrams were divided into 5 segments for analysis as follows: anterior, inferior, septal, apical, and posterolateral. Two techniques of interpretation were used. The first (a point score technique) consisted of independent visual interpretation of computer-processed scintigrams (after contrast enhancement and 20% background subtraction). The peak exercise and delayed images were compared side by side, before and after nifedipine administration. Perfusion defects were graded as follows: 0 = no defect; +1 = mild decrease in thallium-201 uptake; +2 = moderate decrease in thallium-201 uptake; +3 = greatly reduced or absent thallium uptake. The 2nd scintigraphic method used for analysis was a semiquantitative count-ratio technique. A ratio was determined from the counts in each segment over a normal area of myocardium

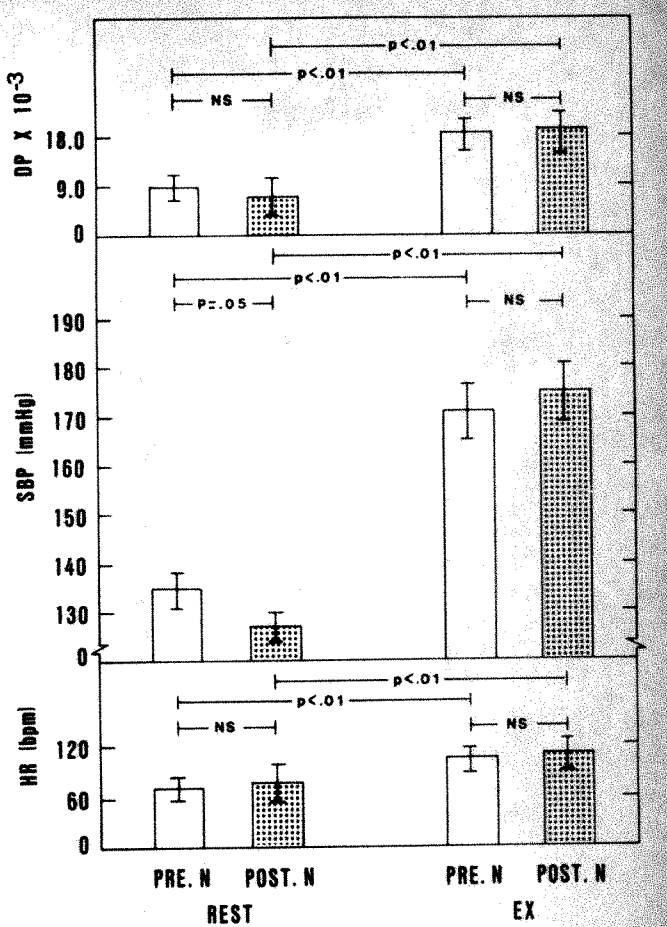

FIGURE 1. Effect of nifedipine on resting and exercise variables. bpm = beats/min; DP = double product (systolic blood pressure X heart rate); EX = exercise; HR = heart rate; N = nifedipine; Pre. N = before administration of nifedipine; Post. N = after administration of nifedipine; SBP = systolic blood pressure (mm Hg).

defined as the zone, in each separate projection, with the highest count density. The regions of interest in the abnormal segments were selected as representative of a portion of the most abnormal perfusion. Assuming that the areas of maximal perfusion in each projection represented normal perfusion, the derived ratio between the two segments multiplied by 100 corresponds to the percent of normal uptake in the abnormally perfused segment. For example, a ratio of 1 would be expected to represent a normal value with homogeneous perfusion. A ratio of less than 80% was considered abnormal.[19] A perfusion defect was considered changed if the compared count ratio varied by 20% or more. Changes in regional perfusion were considered present only if confirmed by both methods of analysis.

Statistical analysis: Data are expressed as mean ± standard error of the mean (SEM). The Wilcoxon test was used as a multiple range test for the comparison of individual pairs of groups. P values of 0.05 or less were considered significant.

Results

Resting Data

Blood pressure, heart rate, and double product: At rest, the heart rate was unchanged (p = NS) after nifedipine (66 ± 3 versus 69 ± 3 beats/min). The supine

systolic blood pressure decreased from 135 ± 4 to 127 ± 3 mm Hg (p = 0.05). The double product was unchanged (9.0 ± 0.6 × 10^3 versus 8.8 ± 0.4 × 10^3) (Fig. 1).

Radionuclide ventriculography: ejection fraction: Eight patients had a normal resting left ventricular ejection fraction (that is, 50% or greater) before nifedipine. Nifedipine slightly but significantly improved the ejection fraction at rest (49 ± 3.6% before nifedipine to 52 ± 3.3% after nifedipine, p <0.05). In 5 patients (33%), it did so by 5% or greater, thereby normalizing the ejection fraction in 2 of them (Table II).

Segmental wall motion abnormalities: Twelve patients had wall motion abnormalities at rest before nifedipine was administered. Four patients had improvement in their wall motion abnormalities at rest after nifedipine was given. No patient had worsening of wall motion. The mean wall motion index at rest was slightly improved after nifedipine, but the difference failed to attain statistical significance (2.2 ± 2.14 versus 2.67 ± 2.32, p >0.05) (Table II).

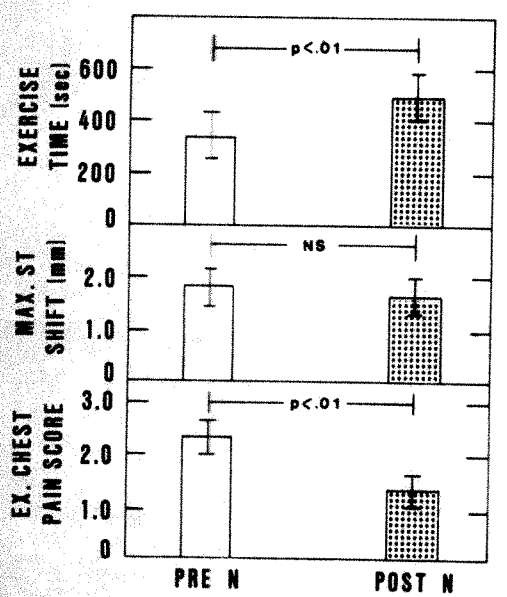

FIGURE 2. Effect of nifedipine on exercise performance. EX. = exercise; MAX. = maximal. Other abbreviations as in Figure 1.

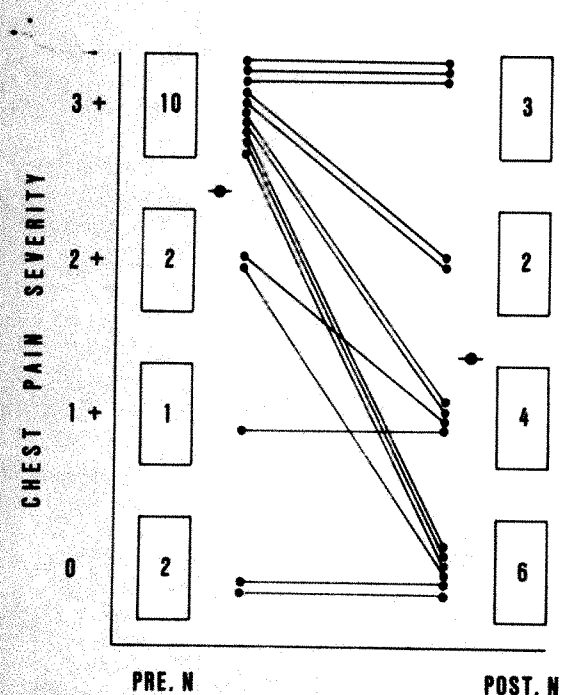

FIGURE 3. Effect of nifedipine on the severity of chest pain at peak exercise in individual patients. 0 = no angina, 1+ = mild angina (subjectively less than the patient's usual severity of chest pain); 2+ = moderate chest pain (usual anginal severity); 3+ = severe chest pain (more than usual severity). The total number of patients in each angina class is shown inside the rectangles.

Exercise Data

Blood pressure, heart rate, and double product: At peak exercise, there was no difference (p >0.05) before and after administration of nifedipine in heart rate (104 ± 6 versus 109 ± 6 beats/min), systolic blood pressure (171 ± 6 versus 174 ± 6 mm Hg) and double product (18.1 ± 1.4 × 10^3 versus 19.2 ± 1.4 × 10^3 mm Hg beats/min) (Fig. 1). In 3 patients, the peak exercise double product decreased after nifedipine was administered in association with an unchanged (2 patients) or increased (1 patient) exercise tolerance. In 2 other patients, the exercise double product remained unchanged after administration of nifedipine despite an improvement in exercise performance (Table I).

Exercise time: The exercise time (Fig. 2) before the oral administration of nifedipine was 343 ± 42 seconds and increased to 471 ± 50 seconds after administration of nifedipine (p <0.01). Exercise tolerance increased in all but 3 patients.

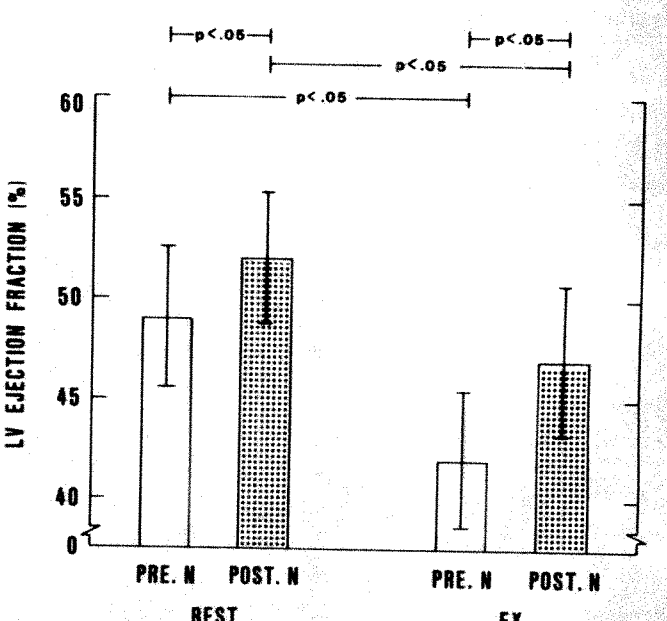

FIGURE 4. Effect of nifedipine on the rest and exercise left ventricular ejection fraction. LV = left ventricular. Other abbreviations as in Figure 1.

Severity of angina: Ten patients (67%) had moderately severe chest pain (3+) at peak exercise before nifedipine, 2 patients (13%) had angina of 2+ severity, 1 patient (7%) had mild angina (1+), and 2 patients (13%) had no chest pain at peak exercise before administration of nifedipine. The severity of chest pain during bicycle exercise was less in 9 (69%) of 13 patients after nifedipine. Four (31%) of the 13 patients became angina-free at peak exercise. No patient had worsening of angina after nifedipine (Fig. 3). The peak exercise chest pain score was less after nifedipine (2.3 ± 0.3 before versus 1.1 ± 0.3 after nifedipine, $p < 0.01$) (Fig. 2).

S-T segment shift: The mean maximal S-T segment shift during exercise (Fig. 2) was 1.8 ± 0.3 mm before and 1.6 ± 0.4 mm after nifedipine (p = NS). Ischemic S-T shifts were present during exercise in 13 patients before nifedipine and in 10 patients after nifedipine. However, in 8 patients, maximal S-T segment shifts improved (greater than 1 mm) (4 patients) or remained unchanged (4 patients) after nifedipine despite an increase in work load.

Ejection fraction: Before the administration of nifedipine there was a significant decline in left ventricular ejection fraction from resting to peak exercise (49 ± 3.6% to 42 ± 3.3%, $p < 0.05$) (Fig. 4). Although a significant decrease in ejection fraction from rest to exercise continued to occur after nifedipine (52 ± 3.3% at rest to 47 ± 3.7% at peak exercise, $p < 0.05$), the peak exercise ejection fraction was higher after nifedipine (47 ± 3.7% after versus 42% ± before nifedipine, $p < 0.05$), with greater than 5% improvement in exercise ejection fraction in 8 patients.

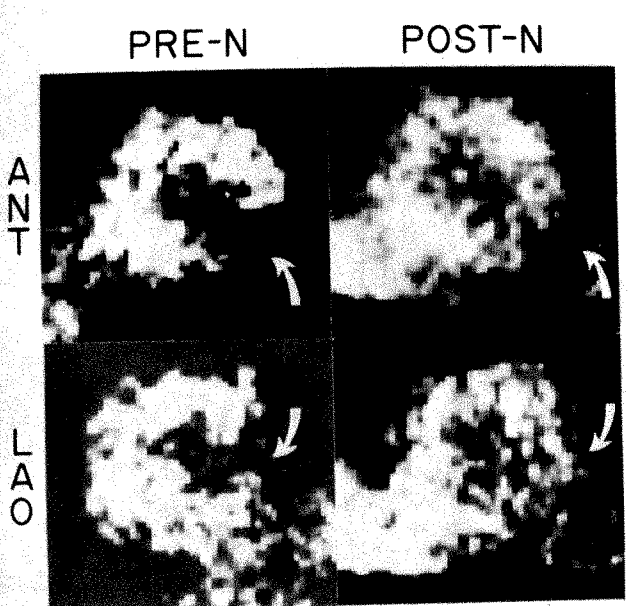

FIGURE 5. Thallium-201 scintigrams taken in the anterior (ANT) and 45° left anterior oblique (LAO) projections immediately after exercise. The 2 scintigrams on the **left** are the exercise studies before administration of nifedipine (PRE-N) and show large perfusion defects in the apical and posterolateral regions of the left ventricle. Five days later, 90 minutes after the oral administration of 20 mg of nifedipine (POST-N) (exercise scintigrams on the **right**), perfusion is markedly improved in the aforementioned regions.

TABLE III Results of Exercise Thallium-201 Scintigraphy in 11 Patients

Case	Peak Ex Results of Thallium-201		
	Point Score		Count/Ratio Changes
	Pre-N	Post-N	
2	9	9	NC
5	9	9	NC
7	6	6	NC
8	6	2	Improved
9	6	4	NC
10	3	3	Improved
11	5	2	Improved
12	2	1	Improved
13	1	1	NC
14	2	2	NC
15	8	7	Improved

Ex = exercise; N = nifedipine; NC = no change; Improved = greater than 20% change.

Wall motion abnormalities: Eleven patients (73%) had deterioration in wall motion with exercise before nifedipine, 3 had no further changes, and 1 remained normal. In contrast, only 7 patients (47%) had deterioration of wall motion with exercise after nifedipine, 5 had no further changes, 2 remained normal, and 1 had improvement. After nifedipine was administered, the exercise wall motion index was also significantly higher than the rest wall motion index (3.0 ± 2.4 versus 2.2 ± 2.1, $p < 0.05$). However, the peak exercise wall motion index was improved after versus before administration of nifedipine (3.0 ± 2.4 versus 4.3 ± 2.3, $p < 0.01$) (Table II).

Exercise Thallium-201 Scintigraphy

All patients showed perfusion abnormalities with exercise before nifedipine was given. Five (45%) of 11 patients had definite improvement of the exercise perfusion defect after nifedipine (Table III).

Of 22 exercise perfusion defects in 11 patients before administration of nifedipine noted by the point score technique, 7 (32%) showed improvement at peak exercise after nifedipine. When the count-ratio technique was used for comparison, 28 defects were noted in the 11 patients. Of these, 7 (25%) had improvement of more than 20% (Fig. 5).

Discussion

This investigation provides objective evidence that nifedipine improves left ventricular performance in patients with coronary artery disease and stable angina pectoris. The drug had a similar beneficial effect on resting and exercise ejection fraction. Furthermore, the exercise-induced regional wall motion abnormalities were less marked after nifedipine. In certain patients, nifedipine appeared to improve the exercise-induced myocardial perfusion defects. In addition, this study confirms the previous observation that nifedipine prolongs exercise duration and decreases ischemia at peak exercise.[7,9,10]

The improved exercise time in these patients was statistically significant and could not be ascribed to a training effect because all patients had undergone several exercise tests previously. Exercise tolerance improved by 37% after nifedipine in the group as a whole. This improvement is within the range (23 to 64%) previously described.[20–23] In addition to the prolongation of exercise time, there was evidence of a reduction in the severity of ischemia as indicated by the lesser severity of angina and the magnitude of S-T segment depression.[24,8] Angina at peak exercise was less severe in 69% of the patients studied, and in 31% of those exercise-induced angina was abolished. In Prempree's series,[23] 4 of 6 patients with stable angina were pain-free at peak exercise on the treadmill despite significantly higher heart rates. The European double-blind or long-term open trials of nifedipine,[20] as well as preliminary results from American studies,[9,10] have demonstrated a significant reduction in the average number of anginal attacks and in the consumption of nitroglycerin in the patients receiving nifedipine compared with results from placebo. Ischemic S-T segment depression was still present in most patients at peak exercise after administration of nifedipine; however, in 53% of the cases the S-T segment shift after administration of nifedipine either improved (greater than 1 mm) or remained unchanged while the work load increased.

Due to its arterial dilating effect, nifedipine decreases systemic vascular resistance and thus the left ventricular afterload while having little effect on preload.[20,30–32] Consequently, the heart rate may increase by reflex mechanism.[33,34] In our group of patients, the resting systolic blood pressure decreased after nifedipine. The peak exercise double product either decreased or remained unchanged despite an increase in exercise duration after nifedipine, suggesting that 1 mechanism by which nifedipine reduced exercise-induced angina and improved performance in those patients was by reducing the double product and thereby myocardial oxygen demand at a given exercise load. Thus, the improvement in exercise-related angina is at least partly due to peripheral effects of nifedipine.

The question regarding the net effect of nifedipine on ventricular function in the presence of critical coronary artery disease has not been sufficiently addressed previously. Contrary to former concern,[11] nifedipine did not appear to have a deleterious effect on left ventricular function. Our investigation demonstrates a significant improvement in the resting as well as the exercise ejection fraction after the administration of nifedipine. The ejection fraction improved by more than 5% in one third of the patients at rest, and in more than half of the patients at peak exercise. Importantly, there was no significant deterioration (ejection fraction decrease by 5% or more) in any patient. In contrast, there was a dramatic normalization of the left ventricular ejection fraction response to exercise after nifedipine was administered to 2 patients (Patients 7 and 9). This clearly suggests that whatever negative inotropic action nifedipine may have does not result in a clinically important effect despite severe left ventricular dysfunction (Patients 2, 4, and 15). The direct negative inotropic effect is probably offset by its arterial dilator effect bringing about a change in baroreceptor tone that results in an increase in heart rate and a secondary increase in contractility. The lack of deleterious effect on myocardial function is also supported by the absence of worsening wall motion at rest or peak exercise after administration of nifedipine. The peak exercise wall motion index was improved after nifedipine, and only 47% of patients had deterioration in wall motion after nifedipine from rest to exercise, compared with 73% before nifedipine.

Can the beneficial effects of nifedipine be fully accounted for by the peripheral and reflex mechanisms? Lichtlen et al.[35,36] demonstrated that nifedipine increased poststenotic perfusion of ischemic areas induced by exercise or rapid atrial pacing. In our study, exercise thallium-201 perfusion scintigraphy was performed in 11 patients and improvement in thallium uptake was noted in 5 (45%). It is therefore suggested that in those patients the distribution of myocardial blood flow may have been improved with nifedipine.

In summary, nifedipine is demonstrated to have a beneficial effect on resting and exercise left ventricular function in patients with coronary artery disease and chronic stable angina. This effect appears to be multifactorial and involves peripheral mechanisms in addition to possible improvement in myocardial perfusion.

Randomized Double-Blind Comparison of Verapamil and Nifedipine in Chronic Stable Angina

V. BALA SUBRAMANIAN, MD, MICHAEL J. BOWLES, MB, MRCP, NARDEV SINGH KHURMI, MBBS, ANTHONY B. DAVIES, MB, MRCP, and EDWARD B. RAFTERY, MD, FRCP

A randomized double-blind crossover trial was performed in 32 patients with chronic stable angina to compare the antianginal actions of verapamil (120 mg 3 times daily) and nifedipine (20 mg 3 times daily). Efficacy was assessed using objective end points obtained by computer-assisted exercise testing and 24 hour ambulatory monitoring for S-T segment shift. Twenty-eight patients completed the trial. The mean exercise time to produce angina improved from 5.7 ± 0.3 minutes (mean ± standard error of the mean) in patients on placebo, to 7.9 ± 0.5 minutes in those on nifedipine and 10.0 ± 0.7 minutes in those on verapamil. Similar improvement was seen in all other objective variables. Generally, verapamil produced mild bradycardia and nifedipine mild tachycardia. Four patients complained of palpitations and angina after ingestion of nifedipine and were identified by ambulatory monitoring to have tachycardia and persistent S-T depression. These opposite effects on heart rate may explain the differences in efficacy between these 2 potent calcium ion antagonists.

The emphasis on drug treatment of angina pectoris has shifted from nitrates to beta-adrenoceptor blocking agents in the last 20 years, and now there is great interest in calcium channel blocking drugs as an additional therapeutic measure in chronic stable angina. This interest is mainly attributable to the work of Maseri, who clearly demonstrated that coronary arterial spasm plays an important part in the genesis of angina[1] and that this spasm is antagonized by the slow calcium channel blocking drugs.[2] There are now 12 drugs that are claimed to have the property of slow calcium channel blockade, but it is not known which are likely to become first line agents in the treatment of angina pectoris.[3]

The 2 most widely used drugs in this group are verapamil and nifedipine. Verapamil was first introduced in 1962 as a coronary vasodilator and was later demonstrated to be a powerful antiarrhythmic agent because of its depressor action on the atrioventricular node.[4] Nifedipine was developed as a specific calcium channel blocking drug and has been shown to be a powerful antianginal agent in vasospastic angina.[5–7] It has also been used in patients with chronic stable angina with variable results.[3,8] Direct comparisons of these 2 drugs in chronic stable angina are considered essential, and we have conducted a randomized double-blind placebo-controlled crossover trial comparing their actions in a large group of patients with chronic stable angina.

Material and Methods

Thirty-two patients (30 men and 2 women aged 40 to 69 years) with chronic stable exertional angina were recruited for the study.

Inclusion criteria: The patients were required to have unequivocal evidence of obstructive coronary artery disease, to have symptomatic stable angina, and to have S-T segment depression and angina on maximal treadmill exercise testing. Coronary artery disease was confirmed by selective coronary arteriography in 21 patients or by transmural myocardial infarction in the 12 months preceding the trial in 11 patients. All had classic angina on exertion relieved by rest and sublingual administration of glyceryl trinitrate with a minimal incidence of 4 attacks/week. All had classic anginal pain on treadmill exercise testing with at least 1 mm S-T segment depression with a slope less than 0.1 V/s in 2 bipolar leads (CM5 and CC5) during exercise. Only patients physically capable and mentally motivated for repeated treadmill exercise were entered into the final trial.

Exclusion criteria: All patients more than 70 years of age and women in the child-bearing age were excluded. Myocardial infarction in the preceding 4 months, unstable angina and severe symptoms that were clinically judged as unsuitable for placebo treatment, overt cardiac failure, resting blood pressure levels in excess of 160/100 mm Hg, and insulin-dependent diabetes mellitus were other exclusion criteria. All patients receiving diuretic drugs, digitalis, and other cardiovascular drugs were excluded, as were patients showing more than 0.5 mm S-T depression on standing, hyperventilation, and the Valsalva maneuver. Patients who did not have classic angina on the initial diagnostic treadmill exercise test with 1 mm S-T segment depression in both bipolar leads were also excluded.

Trial design: All patients underwent a diagnostic exercise test performed without any treatment (26 patients) or 4 weeks after complete withdrawal of long-term medical therapy. Two were taking long-acting nitrates and 4 were taking propranolol (40 mg 3 times daily) before inclusion in the trial. None were given any other cardiac drugs except the trial drugs and sublingual nitrates during the trial period. Sublingual nitrates were only allowed for relief of an anginal episode when it occurred, and patients were clearly and repeatedly instructed not to use them prophylactically and to maintain a diary of their glyceryl trinitrate consumption.

The drugs were administered using a double-dummy technique. During the first 2 weeks (which comprised the placebo run-in phase) the patients took 3 tablets, 1 of verapamil and 2 of nifedipine placebo, 3 times daily. In the crossover phase the 3 tablets were either active verapamil and placebo nifedipine, or active nifedipine and placebo verapamil. This phase was double-blind. All verapamil tablets including placebo were identical in appearance, and all nifedipine capsules including both doses and placebo were identical. The tablets were packed in plastic containers with compartments identifying the day of the week and the time of drug administration.

TABLE I Treadmill Protocol

Stage	Time (min)	Speed (miles/h)	Gradient (%)
1	3	2	0
2	3	3	4
3	3	3	8
4	3	3	12
5	3	3	16
6	3	3	20
7	3	4.5	20

The trial design was a double-blind crossover study of 4 weeks in each treatment period after the 2 weeks placebo run-in period. The dosage schedules were nifedipine 20 mg 3 times daily or verapamil 120 mg 3 times daily, and the randomization was based on a table of random numbers. The active drugs were crossed over at the end of each 4 week period with a 1 week washout period in between.

Formal exercise testing was repeated at the end of the placebo, and each 4 week period of active drug therapy. Twenty-four hour ambulatory monitoring (Oxford Medilog II) and estimation of left ventricular function by systolic time intervals (analyzed by an on-line computer system) were also performed at the end of each period to establish changes in resting heart rate, left ventricular function, and the appearance of conduction defects.

Exercise testing: All tests were performed using a motor-driven treadmill, the speed and gradient of which were regularly calibrated, and the program (Table I) was governed by a computer (Marquette Computer Assisted System for Exercise). Two bipolar leads (CM5 and CC5) were continuously recorded before, during and after exercise in a 25:1 compressed format. Digital printouts of S-T depression at the J point, S-T slope, heart rate, and ectopic count were generated for every minute of the test and for a final analog trend

TABLE II Exercise Test Data on Nifedipine and Verapamil Therapy

	Placebo Period	Nifedipine (20 mg 3 times daily)	Verapamil (120 mg 3 times daily)
Exercise time (min)	5.7 ± 0.3	7.9 ± 0.5	10.0 ± 0.7
Work load (units)	5.6 ± 0.4	13.6 ± 0.9	23.8 ± 1.2
Resting heart rate (beats/min)	74 ± 2	77 ± 2	68 ± 2
Maximal heart rate (beats/min)	125 ± 3	130 ± 3	124 ± 3
Heart rate gain (beats/min)	51 ± 3	53 ± 3	56 ± 2
Heart rate recovery 5 min (beats/min)	53 ± 4	46 ± 2	50 ± 2
Double product (peak)	154 ± 8	159 ± 8	164 ± 6

MS-T/ex. time CC5 (mm)	0.361 ± 0.03	0.242 ± 0.020	0.172 ± 0.016
MS-T/METS CM5 (mm)	0.13 ± 0.014	0.065 ± 0.007	0.049 ± 0.005
MS-T/METS CC5 (mm)	0.12 ± 0.010	0.062 ± 0.006	0.037 ± 0.003
MS-T/O_2 consumption CM5 (mm)	0.036 ± 0.004	0.018 ± 0.002	0.012 ± 0.001
MS-T/O_2 consumption CC5 (mm)	0.033 ± 0.003	0.018 ± 0.002	0.011 ± 0.001
S-T (same ex. time) CM5 (mm)	1.8 ± 0.2	1.0 ± 0.2	0.7 ± 0.2
S-T (same ex. time) CC5 (mm)	1.7 ± 0.2	1.0 ± 0.1	0.6 ± 0.2
Heart rate (same ex. time) (beats/min)	122 ± 3	117 ± 3	106 ± 3
S-T recovery in 5 min CM5 (mm)	1.8 ± 0.2	1.5 ± 0.2	1.4 ± 0.1
S-T recovery in 5 min CC5 (mm)	1.7 ± 0.1	1.6 ± 0.1	1.4 ± 0.1

All values are mean ± standard error of the mean.
Ex. time = exercise time; METS = metabolic equivalents; MS-T = maximal S-T depression; O_2 = oxygen.

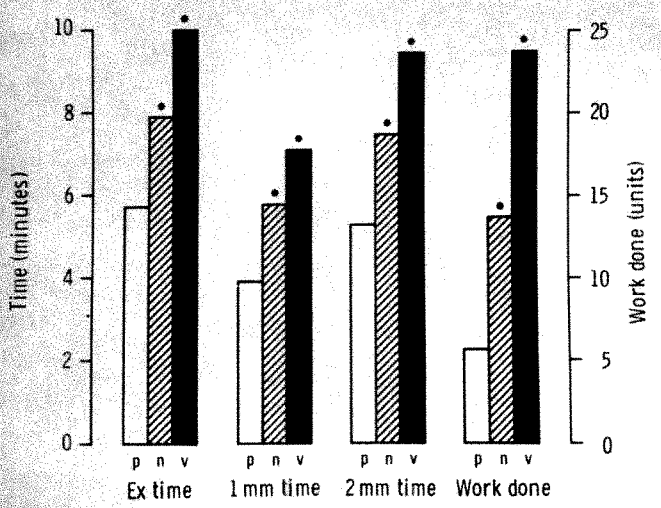

FIGURE 1. Comparison of exercise time (Ex time), time to 1 and 2 mm S-T segment depression, and work done on placebo, nifedipine, and verapamil therapy. n = nifedipine (20 mg 3 times daily); p = placebo; v = verapamil (120 mg 3 times daily); **asterisk** indicates $p < 0.001$ compared with placebo. For standard errors, see Table II.

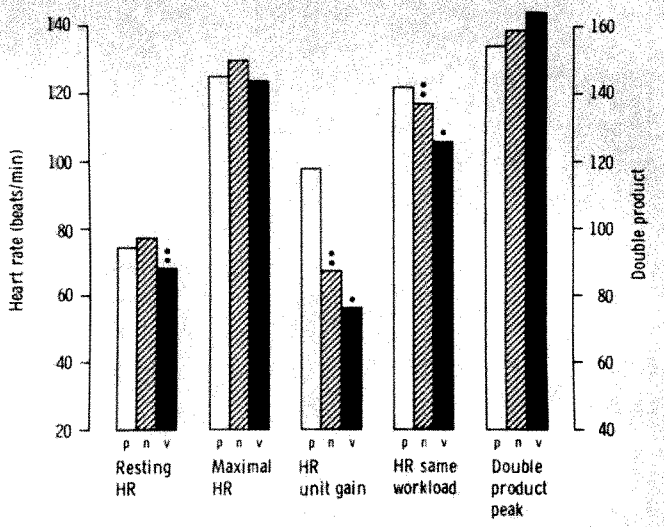

FIGURE 3. Changes in heart rate variables on placebo, nifedipine, and verapamil therapy. Note the mild resting tachycardia (p not significant) produced by nifedipine and the bradycardia by verapamil. Both drugs reduce heart rate unit gain and heart rate at the same work load as placebo, but verapamil has a more significant bradycardiac effect. Neither drug affects the double product at peak exercise. HR unit gain = heart rate gain divided by exercise time. Abbreviations as in Figure 1.

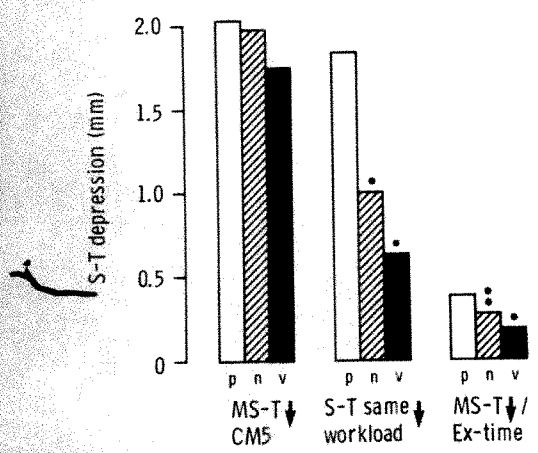

FIGURE 2. Exercise-induced S-T segment changes in bipolar lead CM5 during placebo, nifedipine, and verapamil therapy. **Double asterisks** indicate $p < 0.01$; MS-T = maximal S-T depression. Other abbreviations as in Figure 1.

plot of each complete test. Systolic blood pressure was measured every 3 minutes and at termination of exercise with a mercury-in-glass sphygmomanometer.

The following variables were calculated from the computer printouts[9]:

Time variables were as follows: (1) exercise time required in minutes for production of angina or termination of exercise, (2) work load = distance walked in kilometers multiplied by the sine of the angle of the treadmill in degrees, (3) 1 mm time/2 mm time = time required to produce 1 and 2 mm S-T segment displacement for both bipolar leads CM5 and CC5.

S-T segment variables (for 2 bipolar leads): (1) S-T segment displacement at peak exercise (MS-T), (2) MS-T divided by exercise time, (3) MS-T divided by predicted oxygen consumption, (4) MS-T divided by predicted metabolic equivalents (METS), (5) S-T segment recovery in 5 minutes after exercise, and (6) S-T segment depression at the same exercise time on drug therapy as during placebo.

Heart rate variables were as follows: (1) resting heart rate, (2) maximal heart rate, (3) heart rate gain = maximal heart rate minus resting heart rate, (4) heart rate unit gain = heart rate gain divided by exercise time, (5) heart rate at the same exercise time on drug therapy as during placebo, (6) heart rate recovery in 5 minutes after exercise, and (7) double product = the product of systolic blood pressure and heart rate divided by 100.

All exercise tests were maximal or limited by angina, dyspnea, fatigue, or pain in the legs. All were performed in the morning 90 to 150 minutes after the last dose and after 30 minutes rest in a temperature-controlled laboratory. The standard safety precautions as recommended by the American Heart Association were followed.[10]

Ambulatory monitoring: Continuous ambulatory monitoring of the same 2 leads of the electrocardiogram (CM5 and CC5) was performed using a frequency-modulated tape recorder with a quartz-controlled time channel (Oxford Medilog Mark II) for a minimum of 24 hours. All tapes were analyzed visually for prolongation of the P-R interval or higher degrees of heart block. Mean hourly heart rates were obtained using a computer program. The tapes were then played into a minicomputer that stored minute-averaged values of mean, minimal, and maximal heart rate and S-T segment values for 24 hours on a 5.1/4 inch floppy disc. Software analysis enabled acquisition of objective variables such as maximal S-T depression, episodes of S-T depression over 1 mm in 24 hours, and the number of minutes in which the heart rate exceeded a preset figure (100 beats/min).[11]

Left ventricular function: This function was estimated noninvasively by measuring systolic time intervals with the patient in the supine posture. The first derivative of the electrical impedance cardiogram (dZ/dt) was used as the central arterial pulse wave form. The impedance cardiogram and electrocardiogram were simultaneously fed into a purpose built minicomputer that calculated the preejection period, the left ventricular ejection time, the ratio between left ventricular

TABLE III Probability Values for Placebo, Nifedipine, and Verapamil Therapy

NS = not significant. Other abbreviations as in Table II.

ejection time and preejection period (PEP/LVET ratio), the interval between the peak of the R wave of the electrocardiogram and impedance cardiogram (RZ interval), and the ratio between the amplitude of the impedance wave form and the RZ interval (dZ/dt/RZ ratio).[12] The last 2 variables bear a close correlation to the other systolic time intervals and have been used for serial estimation of left ventricular function.[12–16] Stroke volume and cardiac output were also estimated from the impedance cardiogram.[17]

In this study, we used 100 beat averaging during quiet supine rest with additional averaging of the first 20 beats recorded with breath held in expiration. All studies were performed in the morning after supine rest for 20 minutes.

Statistical analysis of all data was performed with a programmed calculator using Student's paired t test (2 tailed).

Clinical interviews were conducted regularly to detect adverse side effects, which were noted on a standard questionnaire. The project was approved by the Hospital Ethical Committee and informed consent was obtained from all patients.

Results

Thirty-two patients (30 men and 2 women) were entered into the study. Twenty-eight patients completed all phases of the study and all data concern these patients.

Placebo (Fig. 1 to 3, Tables II to IV): All patients discontinued exercise because of angina. The exercise time required to produce angina ranged from 3.3 to 9.9 minutes (mean ± standard error of the mean 5.7 ± 0.3 minutes). The mean resting heart rate was 74 ± 2 beats/min and this increased to a mean maximum of 125 ± 3 beats/min at 5.7 minutes of exercise. The heart rate gain was 51 beats/min and the heart rate increase per minute of exercise was 9.1 beats/min. The peak double product was 154 ± 8 units. The heart rate recovery 5 minutes after exercise was 53 ± 4.2 beats/min. The maximal S-T segment depression in lead CM5 ranged between 1.0 and 4.3 mm, the mean being 2.0 ± 0.2 mm. The mean exercise time required to produce 1 and 2 mm S-T depression was 3.9 ± 0.3 and 5.3 ± 0.4 minutes, respectively. The S-T segment recovered by 1.8 ± 0.2 mm at 5 minutes after exercise. Lead CC5 showed similar values. Twenty-four hour ambulatory Holter monitoring revealed a range of 7 to 29 episodes of S-T depression over 1 mm in 24 hours with a mean of 15 ± 2 episodes. The maximal depth of S-T depression varied from 1.3 to 4.2 mm with a mean of 2.3 ± 0.2 mm. The glyceryl trinitrate consumption was 11.1 ± 2.0 tablets/week.

Verapamil (Fig. 1 to 3): Of the 28 patients who completed the study, 11 became angina-free on treadmill exercise after 4 weeks of treatment. The exercise time ranged from 3.8 to 18.5 minutes (mean 10.0 ± 0.7). This was significantly greater than the mean placebo exercise time ($p < 0.001$). The mean resting heart rate was 68 ± 2 beats/min and the maximal exercise heart rate was unaltered at 124 ± 3 beats/min. The heart rate gain in 10.0 minutes of exercise was 56 beats/min, giving a heart rate increase per minute of exercise of 5.6 beats/min. The heart rate at the same exercise time as placebo was 106 ± 3 beats/min ($p < 0.001$). Heart rate recovery was unaltered at 50 ± 2 beats/min. The standing systolic blood pressure at rest of 110 ± 7 mm Hg during placebo was not significantly altered by treatment with verapamil. The peak exercise systolic blood pressure was 123 ± 7 mm Hg during placebo, and a mild increase to 130 ± 9 mm Hg (p = NS) was observed during therapy with verapamil. The peak double

TABLE IV Holter Monitoring Data on Nifedipine and Verapamil Therapy

Variable	Placebo	Nifedipine	Verapamil	p Value*
Episodes of S-T depression over 1 mm in 24 hours	15 ± 2	15 ± 2 (p = NS)	9 ± 2 (p <0.01)	<0.01
Maximal depth of S-T depression in 24 hours	2.3 ± 0.2	2.1 ± 0.2 (p = NS)	1.7 ± 0.2 (p <0.05)	NS
Minutes (n) in which HR exceeded 100 beats/min in 24 hours	42 ± 5	101 ± 10 (p <0.01)	4 ± 1 (p <0.01)	<0.001
Patients (n) in whom variable 3 exceeded placebo values	. . .	20	1	. . .

* Probability value between verapamil and nifedipine. The p values in parentheses represent the comparison with placebo and the active drug.
HR = heart rate.

product was 164 ± 6 units, but the double product at the same exercise time as placebo was reduced to 122 ± 5 units (p <0.001). The maximal S-T segment depression in lead CM5 ranged from 0.1 to 2.9 mm, the mean value being 1.8 ± 0.2 mm. This S-T depression now occurred at 10.0 minutes instead of 5.7 minutes on placebo, and all the corrected S-T segment variables showed significant improvement. The time required to produce 1 and 2 mm of S-T depression increased to 7.1 ± 0.5 and 9.5 ± 0.7 minutes (p <0.001). The S-T segment values at the same exercise time as placebo decreased from 1.8 ± 0.2 mm to 0.7 ± 0.2 mm (p <0.001). The S-T segment recovery 5 minutes after exercise was 1.4 ± 0.1 mm, and the ratio of peak S-T to S-T recovery was 78%. The S-T segment changes in lead CC5 were similar to those in CM5.

The ambulatory monitoring tapes were analyzed in detail for heart rate and S-T segment changes. The mean hourly heart rates are shown in Figure 4. Verapamil produced a slowing of the heart rate during the entire 24 hours compared with placebo. The mean number of minutes during which the heart rate exceeded 100 beats/min was 42 ± 5 during placebo, and this was reduced to 4 ± 0.2 during verapamil treatment. The mean maximal depth of S-T depression was reduced to 1.7 ± 0.2 mm (p <0.01) and the number of episodes of S-T depression was reduced to 9 ± 2 (p <0.01). The glyceryl trinitrate consumption was reduced significantly (p <0.01), 2.2 ± 0.9 tablets/week during therapy with verapamil.

The systolic time intervals and other indexes of left ventricular function were not altered with verapamil treatment. One patient had pedal edema after 2 weeks on verapamil and after the trial was maintained on verapamil and diuretic drugs without any further deterioration. No conduction defects were noted during this trial. Minor adverse effects included constipation in 6 patients, headache in 2, and giddiness in 1. None were severe enough to warrant withdrawal of treatment.

Nifedipine (Fig. 1 to 3): Of the 28 patients who completed the study, 8 became angina-free on treatment with nifedipine. The exercise time ranged from 3.0 to 12.5 minutes (mean 7.9 ± 0.5). The mean was significantly higher than with placebo (p <0.001) but significantly lower than with verapamil (p <0.01). The resting heart rate was 77 ± 2 beats/min and the maximal heart rate 130 ± 3 beats/min. The heart rate gain was 6.7 beats/min during exercise and the recovery of heart rate in the postexercise period was 46 beats/min. The heart rate at the same exercise time as placebo was 117 ± 3 beats/min. The standing systolic blood pressure at rest was 108 ± 6 mm Hg (p = NS), and the peak systolic blood pressure on exercise was 122 ± 8 mm Hg (p = NS). The peak double product was 159 ± 8 units and the double product at the same exercise time as placebo was reduced to 130 ± 5 units (p <0.01).

The maximal S-T depression in lead CM5 was 2.0 ± 0.2 mm. The 1 and 2 mm times showed an improvement at 5.8 ± 0.4 and 7.5 ± 0.4 minutes, respectively. The S-T depression at the same exercise time as placebo was reduced to 1.0 ± 0.2 mm. The S-T segment recovery was

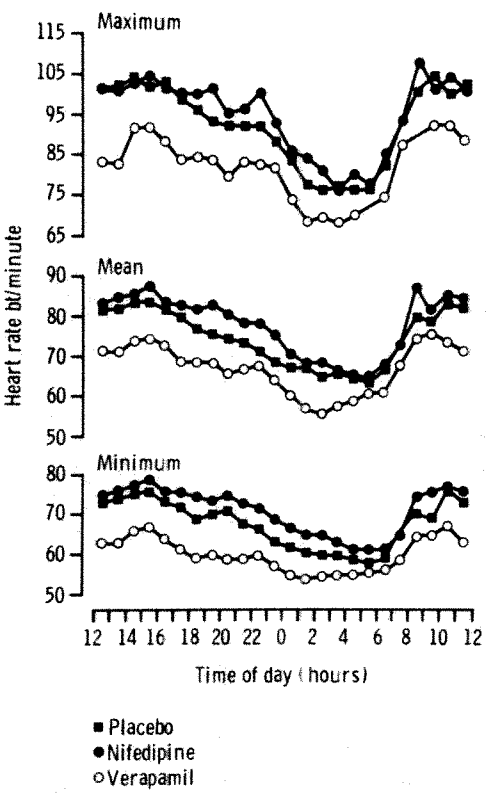

FIGURE 4. Pooled hourly minimal, mean, and maximal heart rates obtained by 24 hour Holter monitoring during placebo, nifedipine, and verapamil therapy. Note the consistent increase in all the heart rate variables on nifedipine therapy and significant bradycardia on verapamil therapy as compared with placebo. bt = beats.

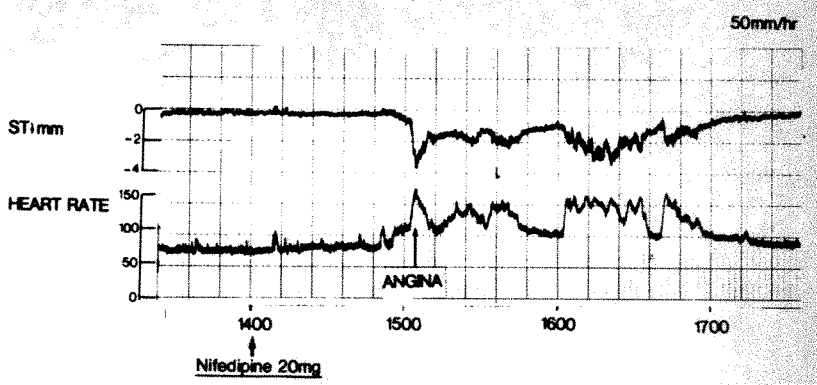

FIGURE 5. An analog trend plot of S-T segment depression associated with marked tachycardia and angina 1 hour after taking 20 mg of nifedipine. The patient was resting during this period. The horizontal axis shows clock time and the vertical axis, calibrated heart rate and S-T depression. The patient took nifedipine at 1400 hours and complained of angina at 1505 hours. Note the increased heart rate and S-T depression lasting almost 2 hours.

1.5 ± 0.2 mm. The S-T segment variables corrected for the increased exercise capacity showed a significant reduction. Lead CC5 showed similar changes.

Twenty-four hour ambulatory monitoring revealed a mild but consistent increase in mean hourly heart rate compared with placebo. The mean number of minutes in which the heart rate exceeded 100 beats/min was 101 ± 10, and this was significantly higher than with both placebo ($p < 0.01$) and verapamil ($p < 0.001$). The mean maximal depth of S-T depression was unaltered at 2.1 ± 0.2 mm, and the number of episodes of S-T depression was 15 ± 2. The glyceryl trinitrate consumption was reduced to 7.2 ± 1.8 tablets/week, but this did not reach statistical significance. The systolic time intervals and other indexes of left ventricular function were not altered with nifedipine therapy.

Three patients had to be withdrawn from the trial during the nifedipine phase without completing 2 weeks of treatment. One patient had accelerated unstable angina that required intraaortic balloon pumping. Another had severe muscular weakness and tremor that disappeared within 24 hours after withdrawal of treatment. The 3rd patient had swelling of the legs, palpitations, and severe headache. Four more patients were withdrawn because of palpitations and angina after taking the drugs, and headache after completing 2 weeks of therapy and all assessments. The ambulatory monitoring of 1 of these patients is shown in Figure 5. There was a rapid increase in heart rate starting about 45 minutes after taking the drug and persisted for about 2 hours. This was accompanied by S-T segment depression and angina. Minor adverse effects not necessitating withdrawal included flushing, tremors, mild pedal edema, and palpitations.

Discussion

Slow calcium channel blocking agents are a heterogeneous group of compounds, with a common action of inhibiting or blocking the slow inward movement of calcium ions across the cell membrane during systole.[18,19] Their site of action is limited to the cell membrane but unlike the beta-adrenoceptor blocking agents, the slow calcium channel blocking drugs vary greatly in chemical structure, pharmacologic action, and pharmacokinetics.[20–22] They have recently been released for general use in the United States, but have been in clinical use in Europe for a long time.[3] Verapamil was one of the first calcium blockers to be used therapeutically, and nifedipine has rapidly gained popularity over the last decade.[23] This study was specifically designed to evaluate objectively the differences in action, efficacy, and safety of these 2 drugs.

Verapamil was first reported by Neumann and Luisada[24] to possess antianginal properties. In their double-blind trial, the drug was administered in a dose of 40 mg 3 times daily and evaluated against placebo in 30 patients with stable angina. Even though a reduction in consumption of nitroglycerin was demonstrated, the study lacked objective end points and therefore no valid conclusions could be drawn. Further studies with objective end points by Sandler et al.,[25] Livesley et al.,[26] and a Danish multicenter group[27] clearly demonstrated that verapamil had an active antianginal action. We performed a single-blind study and double-blind crossover trial of verapamil against placebo in 28 patients, which showed that the drug was more effective than placebo in increasing exercise tolerance and reducing S-T segment changes when used in adequate dosage (360 mg daily).[28,29] We also compared the effects of propranolol with verapamil in a randomized double-blind crossover trial in 22 patients,[30] and investigated the long-term efficacy of verapamil over 1 year,[31] and the potential efficacy and safety of combination with propranolol.[32] Our data, accumulated over 5 years in 100 patients using clearly defined end points, have confirmed that verapamil is a potent and safe antianginal agent.[33–35]

A number of reports have suggested that nifedipine administered orally or sublingually similarly delays the onset of ischemic pain induced by treadmill exercise and minimizes electrocardiographic changes.[36,37] However, in most of these reports,[38,39] the number of patients was small and the control data were inadequate. Ellrodt et al.[3] believed that the data for efficacy of nifedipine in exertional angina were suggestive rather than conclusive. They also commented on the importance of comparing the antianginal efficacy of nifedipine with that of other slow calcium channel inhibitors and with beta-adrenoceptor blocking agents, using adequate numbers of patients and stringently designed protocols with objective end points as test variables. They com-

mented that only data from such comparative studies would permit definition of the role of nifedipine and other slow calcium channel inhibitors in the management of chronic stable angina.

We planned this prospective trial with great care to yield as many objective end points as possible. The trial protocol consisted of a single blind placebo run-in for 2 weeks, after which the patients entered the double-blind randomized crossover phase. Exercise tests, 24 hour ambulatory monitoring, and evaluation of left ventricular function were performed before starting the trial, at the end of the placebo phase, and at the end of each crossover phase. This enabled comparison of the efficacy of each drug with placebo and with each other.

The protocol for exercise testing was carefully designed to minimize subjective bias and observer variation.[40] The entire test was automated, the speed and gradient of the treadmill being controlled by a computer program. Two bipolar electrocardiographic leads were continuously monitored and recorded during and after exercise. The heart rate and S-T segment values were continuously computed and printed out every minute. From these data a number of variables were derived to identify precisely the effects of the drugs on exercise tolerance, onset of S-T segment depression, total S-T segment change, resting, peak and postexercise heart rate, and the double product. Interpatient repeatability of the exercise test was ensured by calibrating the speed and gradient of the treadmill regularly, controlling the laboratory temperature at 24 ± 2°C (mean ± range) and conducting all the tests 90 to 150 minutes after drug administration in the postabsorptive state.

The second leg of the trial was 24 hour monitoring designed to examine the response to uncontrolled environmental influences in these patients. Here again great care was taken to ensure objectivity of results. The tape recorder used was a frequency-modulated machine with an extended low frequency response; we have previously reported our validation of this instrument for S-T data collection.[11] The variables from the tapes were derived by a custom-built computer program. The data included mean, minimal, and maximal hourly heart rates, and S-T segment depression every minute. From the hourly mean heart rates, the number of episodes of S-T depression and the maximal depth of S-T depression could be calculated easily.[41,42]

The effects of both drugs on myocardial contractility were assessed by systolic time intervals, and their effects on the conducting tissue by scanning the ambulatory tapes for prolongation of P-R interval. Neither drug showed any significant change in these variables.

The trial demonstrated a clear difference in the antianginal efficacy of the 2 calcium antagonists in the doses used. Verapamil was more effective in increasing exercise tolerance, decreasing the S-T segment changes and increasing the time required for onset of S-T depression. It produced mild resting bradycardia and a marked reduction in exercise-induced tachycardia. This action on the heart rate was confirmed by the ambulatory heart rates, which showed that during verapamil therapy the mean heart rate exceeded 100 beats/min in only 4 ± 0.2 minutes in 24 hours, as compared with 45 ± 1.2 min/24 hours while on placebo. This effect on the exercise heart rate combined with the slow channel blocking activity appears to be the main basis for the antianginal activity of the drug.

By contrast, the effects of nifedipine varied. The drug produced mild tachycardia and only a moderate improvement in exercise tolerance and S-T segment variables. Adverse effects were frequent, even with the dose of 20 mg 3 times daily used in this trial; the most interesting adverse effect was the development of symptomatic angina with tachycardia appearing within 60 to 90 minutes of taking a 20 mg dose. This occurred in 7 patients, and we objectively demonstrated tachycardia associated with marked S-T depression by ambulatory monitoring in all of them. Similar findings have been reported by other investigators.[43–46] The relatively poor results with nifedipine in comparison with verapamil may be due to this increase in heart rate, which might be controlled by adding a beta-adrenoceptor blocking drug.

The design of this study included fixed doses as an essential feature, and it could be that different results would be obtained with larger doses. However, the doses chosen were based on experience of other extensive trials which suggested that these would be the most effective dosages with minimal adverse effects.

Hemodynamic and Electrophysiologic Effects of Verapamil And Nifedipine in Patients on Propranolol

MICHAEL D. WINNIFORD, MD, ROY V. MARKHAM, Jr., MD,
BRIAN G. FIRTH, MD, D Phil, PASCAL NICOD, MD, and L. DAVID HILLIS, MD

Because the combined use of a beta-adrenergic blocking agent and a calcium antagonist may be beneficial in patients with severe angina, we assessed the hemodynamic and electrophysiologic effects of verapamil or nifedipine in patients receiving oral propranolol. In 26 patients with stable angina receiving oral propranolol (234 ± 230 mg/day, mean ± standard deviation), cardiac catheterization was performed, and variables were measured at baseline and 5 to 10 minutes after (1) intravenous saline solution, 10 ml (n = 6); (2) intravenous verapamil, 0.15 mg/kg body weight to a maximal dose of 10 mg (n = 10); and (3) sublingual nifedipine, 10 mg (n = 10). Cardiac output (by thermodilution) was unchanged after saline solution and verapamil but increased with nifedipine (4.3 ± 1.1 to 5.0 ± 1.4 liters/min, p <0.05). Mean arterial pressure did not change with saline solution or nifedipine but decreased with verapamil. Peak-positive dP/dt was reduced only by verapamil (from 1,086 ± 175 to 926 ± 167 mm Hg/s, p <0.05). Coronary sinus blood flow (by thermodilution) was not altered by saline solution, nifedipine, or verapamil. Verapamil reduced the heart rate (from 63 ± 8 to 60 ± 9 beats/min, p <0.05) and increased the A-H interval (from 108 ± 14 to 129 ± 23 ms, p <0.05). In contrast, nifedipine increased the heart rate (from 65 ± 8 to 71 ± 8 beats/min, p <0.05) but did not change the A-H interval. Left ventricular ejection fraction (by radionuclide ventriculography) was unaltered by saline solution or verapamil but increased with nifedipine (from 0.52 ± 0.13 to 0.57 ± 0.13, p <0.05). In summary, when administered to patients with normal or only mildly depressed left ventricular function who are receiving oral propranolol, nifedipine improves cardiac output and left ventricular ejection fraction without affecting intracardiac filling pressure or atrioventricular conduction. In contrast, verapamil diminishes left ventricular contractility and slows atrioventricular conduction. Thus, the combination of verapamil and propranolol must be used with caution in patients with underlying left ventricular dysfunction or conduction system disease.

The beta-adrenergic blocking agents are efficacious in the treatment of most patients with stable angina pectoris.[1–3] By reducing the heart rate, systolic arterial pressure, and left ventricular contractility, these agents diminish myocardial oxygen demands. More recently, the calcium antagonists, including verapamil and nifedipine, have been shown to exert a potent antianginal effect.[4–8] Like the beta-adrenergic blocking drugs, these agents reduce myocardial oxygen requirements[8–12]; in addition, they may diminish coronary vascular resistance and augment coronary blood flow.[8,12–15] For the patient whose angina is not controlled by beta blockade or calcium blockade alone, a combination of these agents may be particularly effective because their mechanisms of action are, in some ways, complementary. In fact, initial clinical studies have shown that nifedipine and propranolol[16,17] as well as verapamil and propranolol[18] are beneficial in patients with severe angina.

Although combined beta-adrenergic and calcium blockade is potentially beneficial to the patient with severe angina, only a few studies have attempted to define the hemodynamic and electrophysiologic consequences of such combination therapy.[19–22] These

See Table I for an explanation of statistical indicators.
LVEDVI = left ventricular end-diastolic volume index; LVEF = left ventricular ejection fraction; LVESVI = left ventricular end-systolic volume index.

preliminary investigations have suggested that verapamil and nifedipine can be administered safely to the patient already receiving propranolol, but the effects of a verapamil-propranolol combination may differ substantially from those of combined nifedipine and propranolol. The present study was performed to compare the acute hemodynamic and electrophysiologic effects of intravenous verapamil with those of sublingual nifedipine in patients receiving oral propranolol.

Methods

Study patients: The study was performed in 26 consecutive persons (18 men and 8 women, mean age 54 years) referred for cardiac catheterization for the evaluation of chest pain, all of whom were receiving oral propranolol (mean dose 234 mg/day; range 40 to 1,280). In each patient data acquisition was performed 2 to 3 hours after a regularly scheduled dose of oral propranolol. Informed consent was obtained from all patients. Patients with valvular or congenital heart disease, left bundle branch block, or previous coronary arterial bypass surgery were excluded.

Protocol: In each patient, hemodynamic, electrophysiologic, and (in 15 patients) radionuclide ventriculographic measurements were made (1) in the baseline state (that is, on propranolol alone), and (2) after random administration of 1 of 3 pharmacologic agents. All data acquisition was performed before angiography.

Control group ($n = 6$): In these subjects, baseline measurements were accomplished, after which 10 ml of normal saline solution was administered intravenously. Subsequently, all measurements were repeated 5 to 10 minutes later. This group comprised 4 men and 2 women with an average age of 51 years. Their daily propranolol dosage was 177 ± 92 mg (mean ± standard deviation) (range 60 to 320). Coronary arteriography revealed single vessel coronary arterial disease (defined as 70% or greater luminal diameter narrowing) in 3 and triple vessel disease in 3.

Verapamil group ($n = 10$): In these patients, baseline measurements were made, then verapamil (Knoll Pharmaceutical, Whippany, New Jersey), 0.15 mg/kg to a maximal dose of 10 mg, was administered intravenously. All measurements were repeated 5 minutes after administration of verapamil. These 10 patients included 8 men and 2 women with a mean age of 54 years. Their daily propranolol dose was 298 ± 352 mg (range 80 to 1,280). At coronary arteriography 3 had single vessel coronary arterial disease, 3 had double vessel disease, and 4 had triple vessel disease.

Nifedipine group ($n = 10$): After baseline measurements were performed, nifedipine (Bayer Pharmaceutical, Munich, Germany) (10 mg) was administered sublingually, and all measurements were repeated 10 minutes later. Of these 10 patients, 6 were men and 4 were women, with an average age of 54 years. Their daily propranolol dose was 204 ± 104 mg (range 40 to 360). Three had single vessel coronary artery disease, 1 had double vessel disease, and 6 had triple vessel disease.

Variables assessed: *Hemodynamic measurements:* Systemic arterial pressure was recorded through a percutaneous femoral arterial cannula. Left ventricular pressure was recorded with a high fidelity micromanometer-tipped pigtail catheter (Millar Instruments, Houston) advanced to the left ventricle from the femoral artery, and the maximal first derivative of left ventricular pressure (dP/dt) was electronically derived from this pressure trace. Right atrial, pulmonary ar-

terial, and pulmonary capillary wedge pressure as well as forward cardiac output were measured with a flow-directed, balloon-tipped thermodilution catheter (Electronics for Medicine, model 62 00 37) advanced from the femoral vein. An average of 3 to 4 thermodilution measurements of cardiac output was used for the final computations. The variability of thermodilution measurements in our laboratory is ±4%. From these data, systemic and pulmonary arteriolar resistance was calculated.

Coronary blood flow measurements: In each patient, a thermodilution catheter (model CCS-7U-90B, Wilton Webster Laboratories, Altadena, California) was advanced to the coronary sinus from the right basilic vein, and its position was confirmed oximetrically and by the injection of 3 to 5 ml of contrast material. Coronary sinus blood flow was measured with the continuous thermodilution technique.[23]

Electrophysiologic measurements: A tripolar pacing catheter was advanced from the femoral vein and positioned across the tricuspid valve, and atrio-His bundle (A-H) and His bundle-ventricular (H-V) conduction times were measured.[24]

Radionuclide ventriculography: In 15 of the 26 patients, red blood cells were labeled with 30 mCi of technetium-99m sodium pertechnetate using a technique combining features of both in vitro and in vivo labeling.[25] In the remaining 11 patients, radionuclide ventriculography was not performed because the necessary imaging equipment was not available. Scintigraphic data collection was performed with a portable gamma scintillation camera (Series Sigma 420, Ohio Nuclear, Solon, Ohio), as previously described.[26–30] Left ventricular volume and ejection fraction were estimated by a totally nongeometric technique developed and validated in our laboratory.[28–30] All volumes were normalized for body surface area. The inter- and intraobserver variability of these volume measurements in our laboratory is 7.5 and 6%, respectively, and the reproducibility of these measurements over time has been substantiated.[27]

Statistical analysis: All data are reported as mean ± 1 standard deviation. For each variable in the baseline state, the 3 groups were compared with an analysis of variance. For each group (control, verapamil, and nifedipine), each variable at baseline and after drug administration was evaluated with a paired *t* test.[31] This analysis of paired data was performed (1) for the complete groups (6 control subjects, 10 taking verapamil and 10 taking nifedipine) and (2) after excluding the 4 patients who were receiving either a small (less than 100 mg/day) or large (more than 500 mg/day) dose of propranolol (5 control subjects, 8 taking verapamil, and 9 taking nifedipine). In addition, for each variable in each patient, the difference between the value of baseline and after drug administration was determined, and these differences were compared among the 3 groups by analysis of variance. For all analyses, a p value less than 0.05 was considered significant.

Results

In the baseline state, the 3 groups were similar with regard to age, severity of coronary artery disease, propranolol dosage, and all hemodynamic, electrophysiologic, and scintigraphic variables (Tables I and II). Three patients (1 from each group) were receiving less than 100 mg/day of propranolol, and 1 patient in the verapamil group was receiving an unusually large dose of propranolol (1,280 mg/day). With the exclusion of these 4 patients, the control group (n = 5) received a

TABLE III Hemodynamic Variables Before and After Drug Administration in the 22 Patients Receiving 100 to 360 mg/Day of Propranolol

* $p < 0.05$ in comparison with the same pharmacologic agent in the baseline state.
Abbreviations as in Table II.

daily propranolol dose of 200 ± 80 mg (range 120 to 320); the verapamil group (n = 8) received 203 ± 66 mg (range 100 to 320); and the nifedipine group (n = 9) received 222 ± 92 mg (range 120 to 360). For these 22 patients, the baseline characteristics of the 3 patient groups were similar (Tables III and IV).

Hemodynamic alterations: The hemodynamic alterations induced by saline solution, verapamil, and nifedipine for all 26 patients are shown in Table I. Cardiac output did not change with the administration of saline solution or verapamil. In contrast, nifedipine caused a significant increase in cardiac output (Fig. 1). Systemic arterial pressure was not altered by saline solution or nifedipine but was reduced by verapamil; however, the reduction in arterial pressure produced by verapamil did not differ statistically from that produced by nifedipine (Table I). Systemic vascular resistance did not change with saline solution but decreased with both calcium antagonists (Fig. 1).

Mean right atrial pressure was unchanged with saline solution and nifedipine but increased slightly with verapamil, and pulmonary capillary wedge pressure behaved similarly. These changes in right atrial and pulmonary capillary wedge pressure induced by verapamil were not significantly different from those produced by saline solution (Table I). Peak positive left ventricular dP/dt was not altered by saline solution or nifedipine but was reduced by verapamil (Fig. 2).

The results for the 22 patients receiving 100 to 360 mg/day of propranolol are shown in Table III. The hemodynamic changes induced by each of the 3 pharmacologic agents are similar to those described for the entire group.

Effects on coronary sinus blood flow: Coronary sinus blood flow was not altered by any pharmacologic agent (Tables I and III).

Electrophysiologic alterations: For the entire group of 26 patients, verapamil and nifedipine produced opposite effects on the heart rate: it decreased with verapamil and increased with nifedipine (Table II, Fig. 3). However, the reduction in heart rate produced by verapamil was not statistically different from that produced by saline solution. For the smaller group of 22 patients, the reduction in heart rate induced by verapamil did not achieve statistical significance (Table IV). The A-H interval was not altered by saline solution or nifedipine but was prolonged by verapamil (Tables II and IV, Fig. 3). None of the 3 agents altered the H-V interval.

Scintigraphic alterations: Left ventricular end-diastolic volume index was unchanged by the 3 agents (Tables II and IV). End-systolic volume index decreased

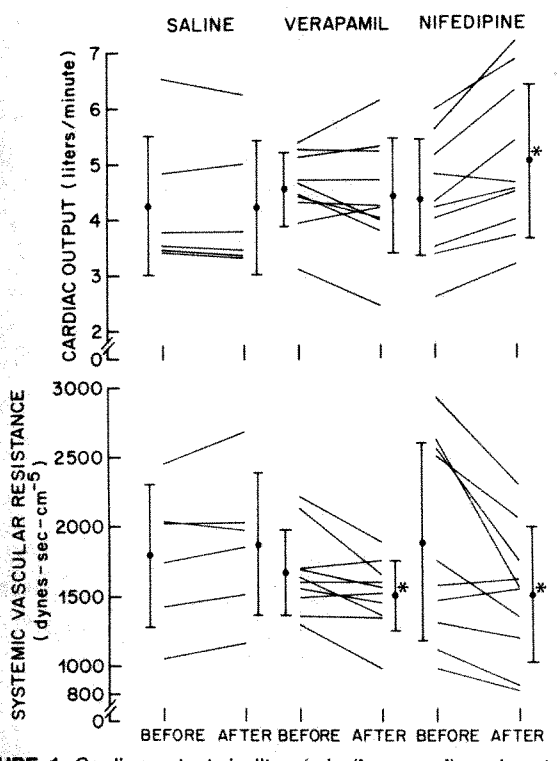

FIGURE 1. Cardiac output, in liters/min (**top panel**), and systemic vascular resistance, in dynes-sec-cm^{-5} (**bottom panel**), before and after the administration of saline solution (**left**), verapamil (**middle**), or nifedipine (**right**). Each **line** represents the data from 1 patient, and the means ± 1 standard deviation are shown on either side of each set of lines. Cardiac output was unchanged by saline solution or verapamil but increased significantly with administration of nifedipine. Systemic vascular resistance was reduced by verapamil and nifedipine. **Asterisks** indicate $p < 0.05$ in comparison with the values before drug administration.

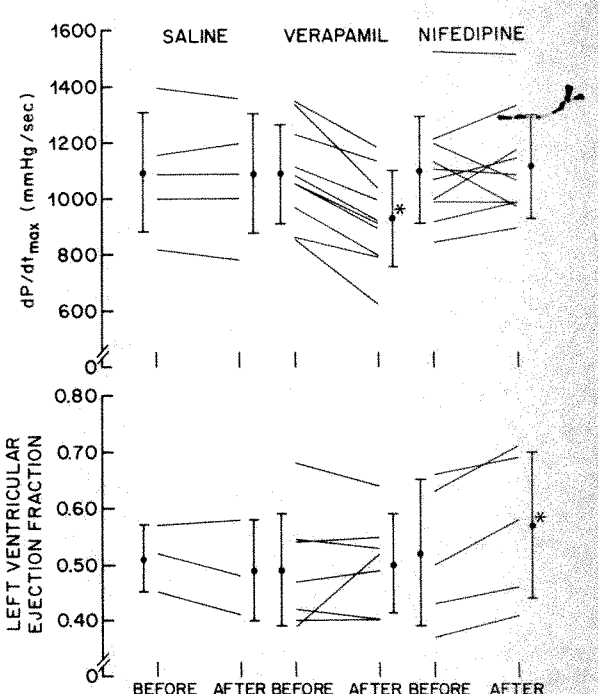

FIGURE 2. Left ventricular peak positive dP/dt, in mm Hg/s (**top panel**), and left ventricular ejection fraction (**bottom panel**), before and after the administration of saline solution (**left**), verapamil (**middle**), or nifedipine (**right**). Each **line** represents the data from 1 patient, and the means ± 1 standard deviation are shown on either side of each set of lines. Left ventricular dP/dt was reduced by verapamil; ejection fraction increased after administration of nifedipine. **Asterisks** indicate $p < 0.05$ in comparison with the same pharmacologic agent before drug administration.

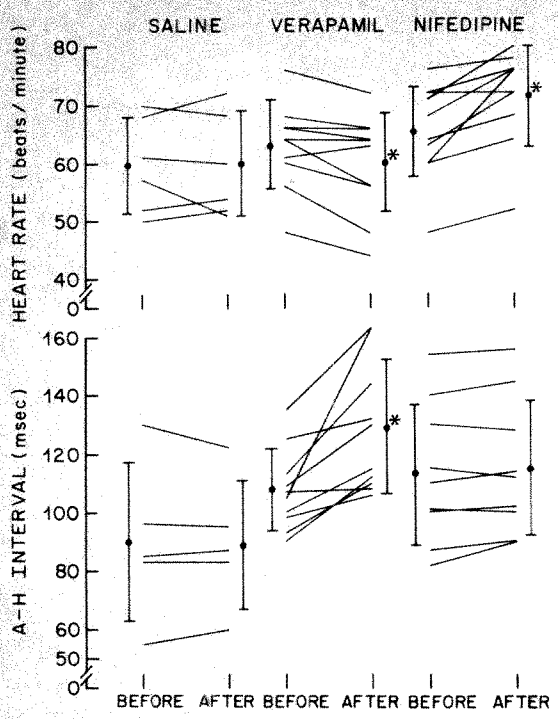

FIGURE 3. Heart rate, in beats/min (**top panel**), and A-H interval, in milliseconds (ms) (**bottom panel**), before and after the administration of saline solution (**left**), verapamil (**middle**), or nifedipine (**right**). Each **line** represents the data from 1 patient, and the means ± 1 standard deviation are shown on either side of each set of lines. The heart rate was reduced by verapamil and increased by nifedipine. The A-H interval was lengthened only by verapamil. **Asterisks** indicate $p < 0.05$ in comparison with the same pharmacologic agent before drug administration.

with nifedipine. Left ventricular ejection fraction was not affected significantly by saline solution or verapamil but increased with nifedipine (Tables II and IV, Fig. 2).

Adverse effects: In one patient who received verapamil, mean systemic arterial pressure decreased from 93 to 68 mm Hg. The heart rate failed to increase, and cardiac output decreased from 3.1 liters/min to 2.4 liters/min. All values returned to baseline within 15 to 20 minutes. This patient was receiving a large daily dose of propranolol (1,280 mg). With this exception, all patients tolerated saline solution, verapamil, and nifedipine without difficulty.

Discussion

Preliminary clinical trials have suggested that the combination of a beta-adrenergic blocking agent and a calcium antagonist may be more effective than either agent alone in the treatment of patients with severe angina.[16–18] The beta-adrenergic blocking agents such as propranolol diminish myocardial oxygen demands by reducing the heart rate, systemic arterial pressure, and left ventricular contractility, but they do not increase the myocardial oxygen supply.[32,33] The calcium antagonists such as verapamil and nifedipine also reduce myocardial oxygen demands (primarily by diminishing afterload); in addition, they augment coronary blood flow by reducing coronary vascular resistance.[8,12,13] Because these agents exert their beneficial effects by different mechanisms, their combination may produce an especially salutary influence on the balance between myocardial oxygen supply and demand.

However, at the same time, combination beta-blocking calcium antagonist therapy could theoretically produce adverse effects. For example, in the patient not receiving a beta-blocking agent, verapamil's negative inotropic and chronotropic influence is counteracted, at least in part, by a reflex increase in sympathetic tone.[34] In the presence of beta blockade this reflex response may be blunted, leading to a reduction in left ventricular performance and cardiac output. Alternatively, in the absence of a beta-blocking drug, nifedipine's powerful effects as a peripheral arterial dilator are partially offset by a compensatory increase in heart rate. In the presence of a beta-blocking agent this reflex tachycardia could be prevented, leading to profound hypotension.[35] Because it is unclear whether the potential beneficial effects of combined beta-blocking calcium antagonist therapy outweigh its potential adverse effects, the present study was performed to explore the hemodynamic and electrophysiologic effects of verapamil and nifedipine in patients already receiving propranolol.

Hemodynamic alterations: In the absence of beta-adrenergic blockade, both verapamil and nifedipine reduce systemic arterial pressure and resistance.[9,10,19,22,34] Because nifedipine is an especially potent vasodilator, it elicits a strong reflex sympathetic response, which offsets its intrinsic negative inotropic effects, so that left ventricular dP/dt may even increase.[36] As a result, nifedipine alone augments cardiac output and left ventricular ejection fraction, even in patients with underlying left ventricular dysfunction.[10,37] In contrast, verapamil causes a decrease in left ventricular dP/dt[38] and a modest increase[34] or no change[22,38] in cardiac output. Its effect on left ventricular ejection fraction is not clear: some studies have demonstrated a decrease,[18] others have shown no change,[37,39] and yet others have shown an increase in this variable.[34]

Although previous studies have attempted to assess the hemodynamic effects of verapamil or nifedipine in patients already receiving beta-adrenergic blocking agents, they have produced conflicting results. Packer et al.[22] administered oral verapamil (120 mg) to patients receiving long-term propranolol therapy and noted a decrease in cardiac index and mean arterial pressure as well as an increase in pulmonary capillary wedge pressure. When this same dose of verapamil was readministered after withdrawal of propranolol, the cardiac index and wedge pressure did not change. Leon et al.[21] noted that a verapamil-propranolol combination produced a reduction in both left ventricular ejection fraction and ejection rate at rest, although verapamil alone produced a similar diminution in ejection fraction. In contrast, Kieval et al.[20] showed that a verapamil-propranolol combination caused no change in cardiac index, left ventricular end-diastolic pressure, left ven-

tricular ejection fraction or maximal dP/dt. Finally, in 12 patients receiving atenolol, Joshi et al.[19] observed no increase in left ventricular ejection fraction and a decrease in dP/dt after administration of nifedipine.

In our study, verapamil or nifedipine was administered on a short-term basis to patients already receiving long-term oral propranolol. Although we made no attempt to ensure full beta-adrenergic blockade in these patients, their dosages of propranolol were those commonly used for the treatment of angina pectoris. Even in the presence of propranolol, nifedipine caused an increase in cardiac output and left ventricular ejection fraction as well as no change in left ventricular dP/dt or intracardiac filling pressure (Tables I and III, Fig. 1 and 2). In contrast, verapamil caused no change in cardiac output or ejection fraction and a decrease in left ventricular dP/dt. In 1 patient (who was taking 1,280 mg/day of propranolol), verapamil induced a sizeable decrease in cardiac output and systemic arterial pressure. Thus, the combination of verapamil and propranolol must be used cautiously, especially in persons who are taking particularly large doses of the latter agent.

Changes in coronary blood flow: The effect of verapamil or nifedipine on coronary blood flow represents a balance between direct coronary vasodilation and reflex vasoconstriction caused by a decrease in myocardial oxygen demands. In most studies verapamil or nifedipine administered alone has caused an increase in coronary blood flow, although Ferlinz et al.[9] demonstrated a slight decrease in coronary blood flow with verapamil. In the present study neither verapamil nor nifedipine caused a significant change in coronary sinus blood flow (Tables I and III).

Electrophysiologic changes: The negative chronotropic effect of nifedipine, like its negative inotropic effect, is offset in vivo by reflex mechanisms, so that nifedipine alone increases heart rate. Atrioventricular conduction is unaltered.[40] In contradistinction, verapamil exerts a powerful negative chronotropic effect, so that there is no reflex increase in heart rate despite a reduction in peripheral vascular resistance.[22,34,38] In addition, atrioventricular conduction is impaired.[40] In the present study, the heart rate increased with nifedipine and decreased slightly with verapamil (Tables II and IV, Fig. 3). In addition, verapamil prolonged the A-H interval in all patients, whereas nifedipine exerted no effect on this variable. Thus, the combination of verapamil and propranolol must be used cautiously in patients with underlying conduction system disease.

In short, the hemodynamic and electrophysiologic alterations induced by verapamil and nifedipine in patients already receiving propranolol are similar to those induced by these agents in the absence of propranolol. Specifically, the alterations produced by verapamil in this study do not differ from those described by Singh and Roche[38] in patients not receiving a beta-adrenergic blocking agent; similarly, the combination of nifedipine and propranolol caused hemodynamic and electrophysiologic changes resembling those induced by nifedipine alone.

Limitations of the present study: This study is limited in several ways. First, it examines the hemodynamic and electrophysiologic effects of a single dose of intravenous verapamil or sublingual nifedipine in patients already receiving long-term oral propranolol. It makes no attempt to assess these effects during the long-term administration of both a calcium antagonist and a beta-adrenergic blocking agent. It is conceivable that the long-term administration of both agents may induce hemodynamic and electrophysiologic effects different from those described in our study. Second, both verapamil and nifedipine were administered in a standardized dose. Although the dosages of each were similar to those used in previous studies,[4,13,15,38,41] it is possible that different effects may be produced by different amounts of each agent. For example, it is possible that a larger dose of nifedipine (that is, 20 mg) could produce adverse effects not observed after 10 mg. Similarly, a smaller dose of verapamil (that is, 0.025 to 0.10 mg/kg) would be expected to exert a lesser effect on contractility and cardiac conduction. Third, most of the patients in the present study had normal or only slightly impaired left ventricular function at rest (Tables I to IV, Fig. 2); it is certainly possible that those with more severe left ventricular dysfunction may respond differently to the combination of propranolol and a calcium antagonist, either verapamil or nifedipine. Lastly, all variables were measured only in the resting state, and no attempt was made to assess the effects of combination therapy on hemodynamic or electrophysiologic variables during exercise.

Clinical implications: The combined use of a beta-adrenergic blocking agent and a calcium antagonist may be beneficial in patients with stable angina who continue to be symptomatic despite therapy with either agent alone. When administered to patients already receiving propranolol, verapamil and nifedipine produce hemodynamic and electrophysiologic changes similar to those produced in the absence of propranolol. Nifedipine improves left ventricular performance without affecting cardiac conduction. In contrast, verapamil diminishes left ventricular contractility and slows atrioventricular conduction. Therefore, the combination of verapamil and propranolol must be used with great caution in patients with underlying left ventricular dysfunction or conduction system disease. Although administration of a nifedipine-propranolol combination is probably preferable in these patients, further studies are needed to establish the safety of this combination in patients with severe left ventricular dysfunction.

Long-Term Follow-Up of Verapamil and Nitrate Treatment for Coronary Artery Spasm

S. BENEDICT FREEDMAN, MB, FRACP, DAVID R. RICHMOND, MB, FRACP, and DAVID T. KELLY, MB, FRACP

Thirty-seven patients with coronary artery spasm and minor coronary atherosclerosis (34) or normal coronary arteries (3) were followed up long-term. All had angina at rest, 32 had nocturnal angina, and 13 had a positive exercise test with S-T elevation. Three had a previous subendocardial infarction; 10 had had serious arrhythmias, which caused syncope in 7. At last review, 21 months (range 1 to 61) after starting therapy, 27 patients continued on verapamil, 314 (120 to 600) mg/day; 4 who did not respond to verapamil were taking nifedipine, 58 (30 to 80) mg/day; and 16 were also taking isosorbide dinitrate, 41 (20 to 80) mg/day. Of the 31 patients on therapy, 21 were asymptomatic, 9 were improved (1 to 4 attacks/month), and 1 had an average of 8 anginal attacks/month; the remaining 6 had stopped therapy and 5 were asymptomatic a mean of 10 (3 to 18) months after stopping. The exercise test became negative in all 12 patients tested on therapy, although 3 required nitrates in addition to verapamil or nifedipine.

In 26 supervised treatment withdrawals in the hospital, a mean of 15 (1 to 55) months on therapy, 10 developed angina in less than 48 hours. Angina recurred in all 6 unsupervised, patient-initiated withdrawals. Failure to stop smoking was positively associated with recurrence of angina on treatment withdrawal ($p < 0.02$).

Long-term treatment of coronary artery spasm with verapamil or nifedipine together with isosorbide dinitrate was well tolerated and effectively relieved angina. No documented serious arrhythmias, syncopal episodes, myocardial infarction, or death occurred during follow-up.

Coronary artery spasm may cause spontaneous angina in patients with normal coronary arteries or with insignificant atherosclerotic disease.[1,2] Therapy with beta-adrenergic receptor blocking drugs is ineffective or may aggravate angina.[3,4] Nitrates relieve acute attacks[1,2] but are less effective for chronic therapy. Both uncontrolled and controlled clinical trials have demonstrated that the calcium-antagonist drugs nifedipine,[4,5] diltiazem,[3,6] perhexiline,[7-9] and verapamil[10-14] effectively prevent angina due to coronary spasm, but the long-term results of medical treatment are not known. Because the symptoms of these patients are known to vary cyclically over long periods it is uncertain whether therapy is required indefinitely. This study reports the outcome of treatment in 37 patients with coronary artery spasm followed up for up to 5 years, and the results of treatment withdrawal in 27 of them.

Methods

Patient population: Thirty-seven patients, 28 men and 9 women (mean age 52 ± 7 years) with coronary artery spasm, were included in the study. All patients fulfilled the following diagnostic criteria: (1) a history of recurrent angina at rest; (2) evidence of transient myocardial ischemia (1 mm or greater S-T elevation or depression on the electrocardiogram or reversible defects on thallium perfusion imaging) or angiographically observed coronary spasm during either spontaneous or ergonovine-provoked angina;[15] and (3) less than 70% luminal diameter narrowing in any coronary artery.

Medical therapy: After diagnosis verapamil therapy was commenced in all patients and the dose was altered according to the symptomatic response. Additional isosorbide dinitrate was given routinely to most patients, and beta receptor blockers were discontinued. Five of the patients who did not respond satisfactorily to verapamil were changed to nifedipine. The patients were followed up for a mean duration of 21 (range 1 to 61) months after starting therapy, 6 for less than 12 months, 18 for 1 to 2 years, and 13 for greater than 2 years. The symptomatic response to treatment was assessed as: (a) good (asymptomatic), (b) satisfactory (1 to 4 attacks of angina per month), or (c) unsatisfactory (more than 4 attacks of angina per month). Seven of the paients with major arrhythmias underwent Holter electrocardiographic monitoring on therapy. Patients with exercise-induced coronary spasm were exercised while on therapy.

Withdrawal from therapy: Twenty-four patients who had responded to therapy for a mean period of 15 (range 1 to 55) months were admitted to the hospital. All therapy, including nitrates, was withdrawn under supervision and S-T segments were monitored for 48 hours. Five other asymptomatic patients discontinued therapy themselves after a mean of 7 (range 2 to 12) months on treatment.

Statistical analysis: Student's t test was used to test for differences in the starting dose of verapamil in those who did and did not require an increase in dose.[16] The exact test of Fisher, Irwin, and Yates[17] was used to determine the significance of differences in proportions of patients with and without recurrent angina on withdrawal of therapy.

Results

Clinical findings (Table I): All 37 patients had had angina at rest for a median period of 5 months (range 1 to 120) before diagnosis. Patients were often incapacitated by angina, and 10 had 10 to 30 episodes weekly. Nocturnal episodes occurred in 32 patients (86%), and 17 (46%) also complained of effort-related angina. Thirty-two patients (86%) were smokers, and 27 of these smoked 20 to 80 cigarettes daily. Hypertension had been treated in 43% with satisfactory control in all. Raynaud's phenomenon and migraine were experienced by approximately one fourth of the patients, and in 4 the 2 conditions coexisted. Anterior subendocardial infarction had occurred in 3. Beta receptor blocking agents had been used before entry to the study in 25 (68%) without improving symptoms, and 16 (43%) were taking nitrates.

Electrocardiographic and angiographic findings (Table II): The resting electrocardiogram was normal in 15 of the 37 patients, while the remainder showed S-T and T wave changes. Twelve lead electrocardiograms recorded during spontaneous angina in 27 showed greater than 1 mm S-T segment elevation in 22 (59%), S-T depression in 4 (11%), and no change in 1. Anterior ischemia predominated. Serious arrhythmias were documented during angina in 10 patients (27%) and caused syncope in 7. Coronary angiography was normal in only 3 patients. In the majority mild coronary atherosclerosis (less than 50% luminal diameter reduction) was present, while 2 patients had stenotic lesions in the range of 50 to 70%.

TABLE I Clinical Features

	Patients	
	n	%
Total	37	...

At rest	37	100
Nocturnal	32	86
On exertion	17	46
Smokers	32	86
Raynaud's phenomenon	8	22
Migraine	10	27
Hypertension	16	43
Thyrotoxicosis	1	3
Previous myocardial infarction	3	8

Ergonovine testing: Twenty-five ergonovine tests were performed in 21 patients and all were positive (Table III). The mean dose of ergonovine was 0.38 mg (range 0.1 to 0.7). S-T elevation occurred in 17 patients and S-T depression in 2. In 12 of 13 patients with a positive ergonovine test and an electrocardiogram recorded during spontaneous angina, the site of ischemia was the same. The remaining patient showed inferior ischemia after ergonovine but anterior and inferior ischemia spontaneously.

Coronary artery involved by spasm: From the occurrence of spasm at angiography and the localization of ischemia during spontaneous and ergonovine-induced angina, the arteries involved by spasm were as follows: the right coronary artery in 12 patients, the left anterior descending in 19, intermediate in 2, the left circumflex in 1, and both the left anterior descending and right coronary arteries in 3.

TABLE II Electrocardiographic and Angiographic Findings

	Patients

* Four patients had 2 ergonovine tests.

Exercise testing: Thirty patients were exercised while they were off therapy (Table III). Thirteen had S-T elevation in at least 1 lead, and in 8 of these with an electrocardiogram during angina at rest the site of spontaneous and exercise ischemia was the same.

Treatment results (Table IV): All patients were commenced on verapamil, mean 260 mg/day in 3 or 4 divided doses. Twenty-four also received oral isosorbide dinitrate, mean 35 mg/day in 2 to 4 divided doses. After dose adjustment 19 patients became asymptomatic, and in 15 symptoms were satisfactorily controlled (1 to 4 attacks of angina per month). Two of these patients had angina after 2 and 4 months of therapy, respectively, in spite of a high dose of verapamil (520 and 800 mg daily) together with isosorbide (50 and 40 mg daily), but they responded to nifedipine and isosorbide. Three other patients did not respond to verapamil and isosorbide. Two of these, taking 320 and 480 mg of verapamil daily, respectively, continued to have ventricular tachycardia or fibrillation with spontaneous angina and were changed to nifedipine. One became asymptomatic; the other had 1 to 4 attacks of angina per month for 5 months and then became asymptomatic. The third patient failed to respond satisfactorily to verapamil or nifedipine, and continued to have an average of 8 episodes of angina per month while maintained on verapamil, 440 mg daily. The mean daily dose of nifedipine in the 4 patients who continued the drug was 58 mg (range 30 to 80), and 3 also took isosorbide 50 (range 20 to 80) mg daily.

TABLE IV Medical Therapy

TABLE V Results of Withdrawal From Therapy in 24 Patients

Supervised withdrawal	24 patients
Withdrawals (n)	26*
Recurrent angina <48 hours	10
Unsupervised withdrawal	5† patients
Withdrawals (n)	6‡
Recurrent angina <48 hours	2
Recurrent angina 2–4 months	4

* Two patients had 2 withdrawals.
† Two of the 5 also had supervised withdrawals.
‡ One patient had 2 withdrawals.

Twenty-seven patients continued on verapamil therapy for the whole period of follow-up; in 14 the dose was increased from a mean of 228 mg/day to 359 mg/day for symptomatic relief. Thirteen on a mean dose of 320 mg/day required no increase. The starting dose in the 14 patients who required an increase was significantly lower than in the 13 who did not (228 ± 88 versus 320 ± 71 mg/day, $p < 0.01$).

Of 12 patients who had a positive exercise test off therapy, a repeat test was negative on verapamil alone in 9 and became negative in the other 3 when nitrates were added to verapamil. In 3 a relationship was demonstrated between the plasma concentration of verapamil and the prevention of exercise spasm.[18] Twenty-four hour Holter recordings during therapy performed in 7 of the patients with a history of major arrhythmia showed no recurrence in any.

In 14 patients angina recurred as a result of a missed or late dose, or because of early timing of the last dose at night. This was most noticeable in the first month of therapy. Side effects were few and minor, and no patient required discontinuation of therapy. Three patients on verapamil complained of constipation, which responded to fecal softeners. One developed symptomatic hypotension late in the course of therapy, and this responded to reduced dosage. One patient on verapamil and 1 on nifedipine complained of fatigue, and 2 patients on nifedipine complained of headache.

Withdrawal from therapy (Table V): Twenty-four patients were admitted to the hospital for supervised withdrawal from therapy. Two patients had 2 withdrawals, making a total of 26 withdrawals in the 24 patients. Fifteen had no recurrence of angina or ischemic electrocardiographic changes. In 9 angina recurred within 48 hours, but in 2 only during an exercise test. In 7 of the 9 patients electrocardiographic changes accompanied angina. Five patients stopped treatment spontaneously, one of them on two occasions. Pain recurred in all 6 patients 24 hours to 4 months after withdrawal. Recurrence of angina on withdrawal was not influenced by the length of treatment or whether nitrates had been given in addition to verapamil. Only smoking was associated with recurrent angina. Fourteen of the 16 recurrences of angina were in smokers, whereas only 4 of the 16 patients without angina recurrence were smokers ($p < 0.02$).

When patients with recurrent angina recommenced therapy, they responded as before. One patient with recurrent angina declined further therapy. Six without angina did not recommence therapy, and 5 of these remained asymptomatic for a mean period of 10 months (range 3 to 18). The other had frequent angina 13 months after stopping therapy but responded when it was recommended.

Long-term follow-up (Table IV): At last review a mean of 21 months (range 1 to 61) after starting treatment, 27 patients were taking verapamil in a mean dose of 314 mg/day and 4 were taking nifedipine, 58 mg/day. Sixteen were taking additional isosorbide dinitrate, 41 mg/day. Twenty-one of the 31 treated patients were asymptomatic, 9 had only 1 to 4 episodes of angina monthly, and 1 had an average of 8 episodes of angina monthly. Six patients who had responded well to initial therapy were not on treatment at a mean of 28 months (range 4 to 47). Five remained asymptomatic and the 6th preferred to take nitroglycerin for angina. Of the 32 smokers on entry to the study, only 9 continued smoking.

Two patients were readmitted to the hospital for recurrent angina while on therapy. In one of these pindolol had been started for hypertension, and when it was discontinued the patient became asymptomatic. The other responded when verapamil was changed to nifedipine. Myocardial infraction or syncope did not occur during follow-up and there were no deaths.

Discussion

This study of a large group of patients with coronary artery spasm without severe coronary atherosclerotic obstruction shows that long-term therapy with verapamil or nifedipine is effective. Most patients responded well to verapamil and, if they did not, to nifedipine, emphasizing that when one calcium antagonist drug is ineffective at appropriate dosage a patient may respond to another. The therapeutic efficacy of verapamil is comparable to that in other reports.[10–14] No patient had to discontinue verapamil therapy because of side effects. As the period of follow-up is long, with high dosage in some patients, the lack of side effects from verapamil is an important finding; this has been reported previously.[19]

Associated isosorbide dinitrate therapy: Isosorbide dinitrate was given to almost 2/3 of patients in this study but was not effective by itself, as has been shown by others.[4,20] Most published studies on the management of coronary spasm have described the use of a single drug. In this study, some patients appeared to respond better to combined therapy with a calcium antagonist and isosorbide than to either drug alone. Similar findings were noted in another study.[14] As nitrates appear to act at a different site in vascular smooth muscle from calcium antagonists,[21] an additive or synergistic effect may explain the beneficial effect of combined therapy.

Effectiveness of verapamil: This was an open trial, so the response to therapy could be partly due to a placebo effect or the spontaneous cyclic remission of symptoms known to occur in this condition.[22] An effect from therapy was inferred because angina often occurred after a late or missed dose or after supervised withdrawal of verapamil, while an increase in the dosage often improved the clinical response. In another study the plasma concentration of verapamil was related to the prevention of exercise-induced coronary spasm, which also suggests a drug effect.[18] Double-blind cross-over trials confirm that verapamil is effective for coronary spasm.[11,23]

Role of beta-blocking drugs: Beta-blocking drugs were tried in 68% of our patients before diagnosis but did not reduce the frequency of angina. In 1 patient successfully treated with verapamil, angina recurred when a beta blocker was introduced for coexistent hypertension and abated when it was stopped. The lack of effect or aggravation of symptoms by beta blockers in patients with coronary spasm has been commented on by others,[2,3,12] and Robertson et al.[24] recently confirmed this in a double blind trial. Beta blockers should not be used in patients with coronary spasm.

Clinical features: The clinical findings in our patients are similar to those of previous reports.[2,20] Nocturnal angina was present in 85%, a history of Raynaud's disease or migraine in 25%, and mild hypertension in 43%. In contrast to previous reports nearly half of our patients complained of exercise-induced angina, suggesting that exertional spasm may occur frequently as has been reported elsewhere.[18] Most patients (86%) smoked cigarettes, but the mechanism whereby smoking may exacerbate symptoms is not known. When patients were admitted to the hospital acutely and stopped smoking anginal attacks continued, but those who continued to smoke long-term were more likely to develop angina when therapy was stopped. The cessation of smoking by a large number of patients may have beneficially influenced the long-term response to therapy, and is clearly part of the optimal treatment of these patients.

The clinical characteristics of patients with variant angina without significant coronary atherosclerosis are thought to differ from those of patients with severe coronary disease.[2] In the present study, the frequent finding of exertional angina and abnormal resting electrocardiogram, the large proportion of men, the preponderance of left coronary spasm, and the occasional occurrence of myocardial infarction emphasize that this difference may not be distinguished clinically. Coronary arteriography is mandatory for diagnosis and management.

Treatment withdrawal: Over half of the successfully treated patients did not develop angina when therapy was withdrawn at a mean of 15 months. Six remained off therapy and 5 were free from angina 10 months later. In several patients who did not develop angina on withdrawal treatment was recommenced because of previously documented malignant arrhythmias or because they desired to continue therapy. The reason for remission of symptoms in patients with coronary spasm is not known. As this condition is cyclical it is reasonable in asymptomatic patients who have

never had malignant arrhythmias or infarction to discontinue therapy under supervision after about 1 year.

Clinical implication: Patients with coronary artery spasm and minor coronary atherosclerosis have recurrent and disabling angina and are at risk from ventricular arrhythmias and myocardial infarction. Treatment with verapamil or nifedipine and nitrates is effective in the long-term and may prevent these life-threatening complications. Treatment can be withdrawn under supervision in certain patients without recurrence of angina.

Pharmacokinetics of Verapamil: Experience With a Sustained Intravenous Infusion Regimen

MICHAEL J. REITER, MD, PhD, DAVID G. SHAND, MB, LINDA M. AANONSEN, BS, ROBERT WAGONER, BS, ELIZABETH McCARTHY, RN, and EDWARD L. C. PRITCHETT, MD

Disappearance kinetic characteristics of verapamil were determined in 9 patients after a single intravenous dose. From the pharmacokinetic variables determined, we designed an intravenous regimen to maintain a plasma verapamil concentration of 150 ng/ml consisting of (1) a loading bolus (10 mg over 2 minutes), followed by (2) a rapid loading infusion (0.375 mg/min) for 30 minutes, and finally (3) a maintenance infusion (0.125 mg/min). We tested this regimen in 7 patients for 2 to 12 hours, and found it to be safe and to produce stable prolongation of the P-R interval. Verapamil concentration was highest immediately after the bolus administration and was prevented from falling below 67 ng/ml by the rapid infusion. Maintenance concentration remained between 77 and 156 ng/ml for all patients, and averaged 122 ng/ml.

Transient and slight decreases in brachial blood pressure and sinus cycle length occurred coincident with the maximum verapamil concentration. Maximum P-R prolongation lagged behind peak plasma concentration but was sustained for the duration of the infusion. Prolongation of the P-R interval was not significantly different at the end of the infusion from that 90 minutes after the start of the regimen. No patient demonstrated significant side effects, arrhythmia, or clinically important hypotension. Although the specified regimen produced a final concentration averaging 125 ng/ml, it is predicted that infusion regimens producing other plasma concentrations can be similarly devised by changing the bolus, rapid loading infusion, and maintenance infusion doses in proportion to the desired final plasma concentration.

Verapamil is a prototypical slow channel blocker recently approved for intravenous use for treatment of supraventricular tachycardia. In controlled studies, intravenous verapamil has been shown effective in terminating paroxysmal supraventricular tachycardias[1–3] and in slowing the ventricular rate during atrial fibrillation.[1,3–6] In addition, verapamil may be useful in classic and variant angina pectoris, acute myocardial infarction, and hypertensive emergencies.[7,8]

Verapamil slows atrioventricular (AV) nodal conduction velocity (negative dromotropic effect) and prolongs AV nodal refractoriness.[9–15] These effects, which are brief after intravenous bolus verapamil,[3,4,6,11] no doubt contribute to the efficacy of verapamil in the therapy of supraventricular tachycardias. Under certain circumstances (such as control of ventricular rate in atrial fibrillation in a postoperative patient) a sustained negative dromotropic effect may be desirable. Oral verapamil has a more prolonged negative dromotropic action than intravenous bolus verapamil,[12,13] but its efficacy as an antiarrhythmic agent remains undetermined[14,15] and it was only recently approved for clinical use. The present study describes our experience with a concentration-maintaining regimen of intravenous verapamil that provides a sustained negative dromotropic action.

Methods

Patients: Thirteen subjects (8 men and 5 women; mean age 40 years) were included in this study. Three of the 13 subjects were normal volunteers; the other 10 were patients who had paroxysmal supraventricular tachycardia but had sinus rhythm at the time of the study. No attempt was made to define the mechanism of the supraventricular tachycardia, although a delta wave indicative of the Wolff-Parkinson-White syndrome was intermittently recorded during sinus rhythm in 1 of the patients. Associated cardiac findings were mild hypertension (2 patients), mild aortic regurgitation (1 patient), and mitral valve prolapse (1 patient). Three patients had first degree AV block (P-R interval of 0.21, 0.21, and 0.24 second, respectively). No patient had congestive heart failure

and none had renal or hepatic dysfunction by clinical findings and serum chemistry values.

Digoxin was discontinued at least 1 week and all other cardioactive drugs at least 48 hours before study. All studies were conducted while the patients had normal sinus rhythm.

Administration of verapamil: Intravenous bolus injection: Nine subjects received 10 mg of verapamil (Isoptin,® Knoll Pharmaceutical, Whippany, New Jersey) in 4 ml of isotonic sterile saline solution delivered over 2 minutes by way of a running intravenous line through a 20 gauge Teflon® cannula inserted into a superficial arm vein. Serum for verapamil assay was obtained from a 20 gauge Teflon cannula positioned in the opposite forearm. Blood pressure and electrocardiographic intervals were recorded as each blood sample was drawn.

Intravenous sustained infusion: Plasma verapamil levels after bolus verapamil administration were fitted to a 2 compartment model and the pharmacokinetic variables were determined using a computer-assisted least-squares fitting of the log verapamil concentration versus time data. These pharmacokinetic variables were then used to devise a 3 stage concentration-maintaining regimen of intravenous verapamil by the method of separate exponentials[16]: *Step 1:* priming injection, verapamil 10 mg over 2 minutes; *Step 2:* rapid loading infusion, verapamil 0.375 mg/min for 30 minutes; *Step 3:* maintenance infusion, verapamil 0.125 mg/min. The rapid loading and maintenance infusions were obtained from a concentration of 0.375 mg verapamil per milliliter of sterile isotonic saline solution delivered at a rate of 60 and 20 ml/h, respectively, by a gravity fed controller (IVAC 230) through a 20 gauge Teflon cannula inserted into a superficial arm vein.

Plasma for verapamil assay was obtained from another 20 gauge cannula in the opposite arm. Blood pressure and electrocardiographic intervals were obtained as each blood sample was drawn.

Verapamil assay: Blood samples were placed in heparinized glass tubes and immediately centrifuged. The plasma was then separated, frozen, and stored at −20°C until assay. Plasma verapamil and norverapamil were measured using the high pressure liquid chromatographic assay described by Harapat and Kates.[17] The efficiency of the extraction technique was consistent and averaged 90% for verapamil and 76% for norverapamil. The assay was linear to at least 20 ng/ml, with a coefficient of variation of 7% for verapamil and 23% for norverapamil.

Electrocardiographic monitoring: A modified electrocardiographic lead II (left shoulder negative, cardiac apex positive) was displayed continuously using a Hewlett-Packard model 78100A and 78101A telemetry transmitter and receiver and a model 780-6A oscilloscope. Using an Elema Mingograf 8 channel recorder, an electrocardiographic rhythm strip was recorded at a paper speed of 100 mm/s at 15 minute intervals during the hour before the patients were given verapamil and as each blood sample was drawn. The P-R interval and cardiac cycle length were measured by hand and represent the mean of 7 to 10 consecutive heartbeats (rounded to the nearest millisecond) at each time interval. The electrocardiographic intervals for the control period were calculated as the mean of the intervals measured at the 5 different times during the 1 hour control period.

Blood pressures were determined by the cuff method immediately after each electrocardiographic rhythm strip was obtained.

Statistical methods: Changes in P-R interval, sinus cycle length, and blood pressure were tested for significance with the Wilcoxon signed rank order test or the sign test.

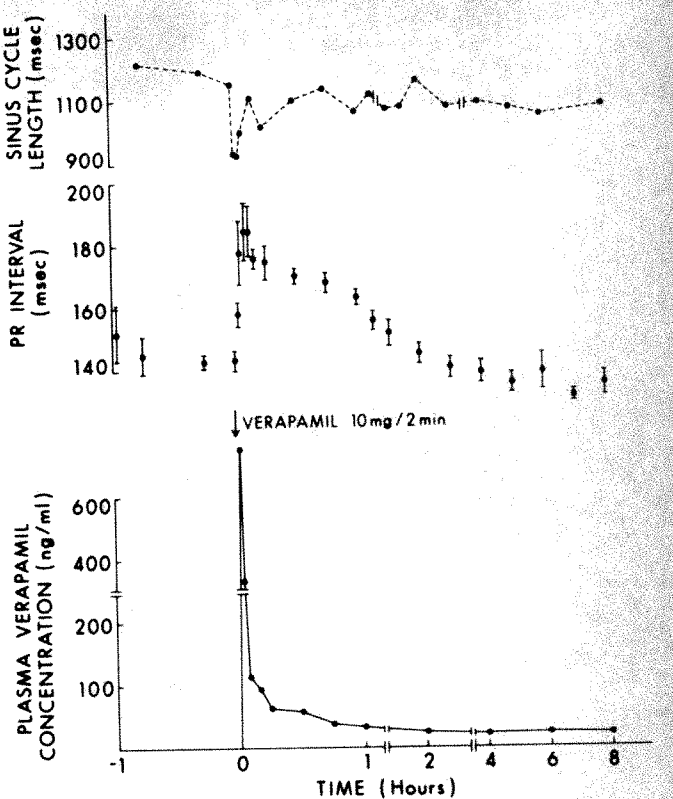

FIGURE 1. Patient 4. Plasma verapamil concentration, P-R interval, and sinus cycle length are shown versus time after administration of 10 mg of verapamil (given as a single intravenous dose over 2 minutes).

Results

Bolus Infusion

Administration of 10 mg verapamil as a single intravenous dose over 2 minutes resulted in peak plasma verapamil levels that occurred within 3 minutes after the start of drug administration (Fig. 1) and that varied widely (range 116 to 752 ng/ml; mean 426). The disappearance of verapamil fitted a 2 compartment model with a volume of distribution (central compartment) equal to 10.8 liters and a clearance rate equal to 47.6 liter/h. The kinetic variables that produced the best fit to the plasma concentration-time data are shown in Table I.

Blood pressure and sinus cycle length decreased slightly but significantly immediately after the end of verapamil administration but then returned to normal. Mean systolic blood pressure decreased 17 ± 13 mm Hg from a control value of 126 mm Hg. Mean sinus cycle length decreased from a control value of 1,003 ± 178 ms (heart rate 60 beats/min) to 801 ± 140 ms (heart rate 75 beats/min). No patient developed sinus tachycardia, although 1 patient developed an accelerated junctional rhythm (cycle length 566 ms). No patient developed AV nodal block, symptomatic hypotension, or side effects. Prolongation of the P-R interval was noted at 2 minutes, but maximum prolongation (125% of control P-R interval) lagged behind peak plasma verapamil concentration and occurred 5 to 30 minutes after the start of the infusion in all 9 patients (Fig. 1). The pro-

TABLE I Pharmacokinetic Variables Derived From a Single Intravenous Dose of 10 mg of Verapamil in 9 Subjects

V_d = Dose/(A_0 + B_0) = 10.8 liters
Cl = Dose/AUC, where AUC = $A_0/\alpha + B_0/\beta$ = 47.6 liters/h.

α = rate constant for the early distribution phase; A_0 = zero-time intercept of the α-phase; AUC = total area under the plasma concentration-time curve; β = rate constant for the terminal phase; B_0 = zero-time intercept of the β-phase, where the decline in measured plasma concentration (C_t) after a single intravenous injection is described by the expression $C_t = A_0e^{-\alpha t} + B_0e^{-\beta t}$; Cl = total clearance of verapamil; SD = standard deviation; V_d = volume of distribution (central compartment).

longation of the P-R interval began decreasing 30 minutes after verapamil was administered. The P-R interval 90 minutes after intravenous administration of verapamil differed from the control value by less than 5%.

Sustained Infusion

From the average kinetic variables calculated, the method of separate exponentials was used to simulate various infusion regimens. The final regimen selected was designed to rapidly achieve and maintain a plasma verapamil concentration of approximately 150 ng/ml. The decrease in concentration (because of rapid drug distribution) before steady state is reached (Fig. 2, bolus plus maintenance infusion) was prevented by a rapid loading infusion. The rapid infusion was chosen so that the verapamil concentration remained within the arbitrary limits of 100 and 175 ng/ml during the loading infusion. The final loading infusion selected was a multiple of the maintenance infusion to simplify delivery. Simulations of the plasma concentration for the bolus alone, the bolus plus the maintenance infusion, and the sum of the bolus, maintenance, and rapid loading infusions together are shown in Figure 2. This regimen has been tested in 1 patient each for 2 and 4 hours, in 2 patients for 6 hours, and in 3 patients for 12 hours. Mean and extreme values of plasma verapamil concentration are shown in Figure 3.

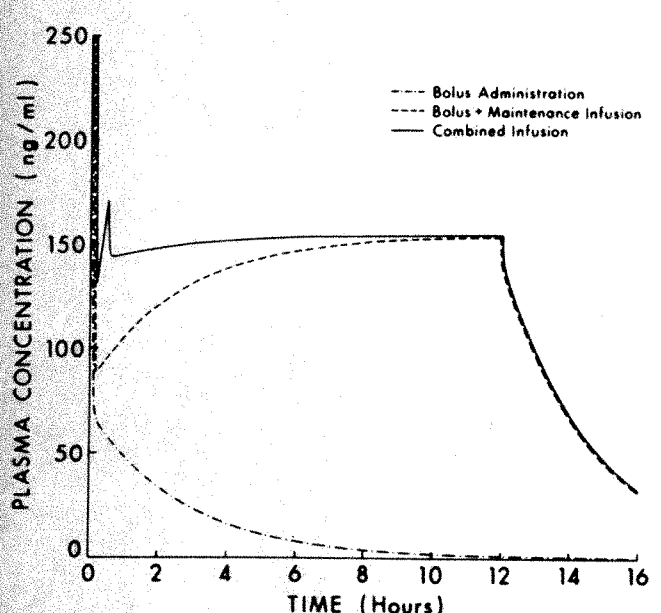

FIGURE 2. Simulations (utilizing the method of separate exponentials) of plasma verapamil concentration versus time are presented for the bolus (10 mg over 2 minutes) alone, the bolus plus the maintenance (0.125 mg/min) infusion, and the sum of the bolus, maintenance, and rapid loading (0.375 mg/min for 30 minutes) infusions.

Plasma verapamil concentration: Peak verapamil concentrations were comparable to those obtained during bolus administration (Table II). Plasma verapamil concentrations reached their nadir 5 to 10 minutes after the start of verapamil administration but did not fall below 67 ng/ml in any patient and averaged 133 ± 45 ng/ml. At the end of the rapid loading infusion, the mean plasma verapamil concentration for the 7 patients was 157 ng/ml (range 114 to 227). This contrasts with mean plasma verapamil concentrations of 81 and 58 ng/ml, respectively, 10 and 30 minutes after a single bolus administration.

Plasma verapamil concentration during the maintenance infusion remained relatively constant for each patient and ranged from 77 to 174 ng/ml (mean 122 ± 21) for all patients. The variation in concentration did not appear to be related to differences in patient weight. There was no apparent increase in plasma verapamil concentration during the infusion.

Norverapamil concentration: Norverapamil, the n-demethylated metabolite of verapamil, reached measurable plasma levels 30 to 60 minutes after the start of verapamil administration in all patients. Mean norverapamil concentration at the end of the infusion was 33 ± 7 ng/ml (range 19 to 39). Maximum norverapamil levels occurred within 1 hour after terminating the infusion and ranged between 30 and 41 ng/ml for all patients. The 3 individuals who received 12 hour infu-

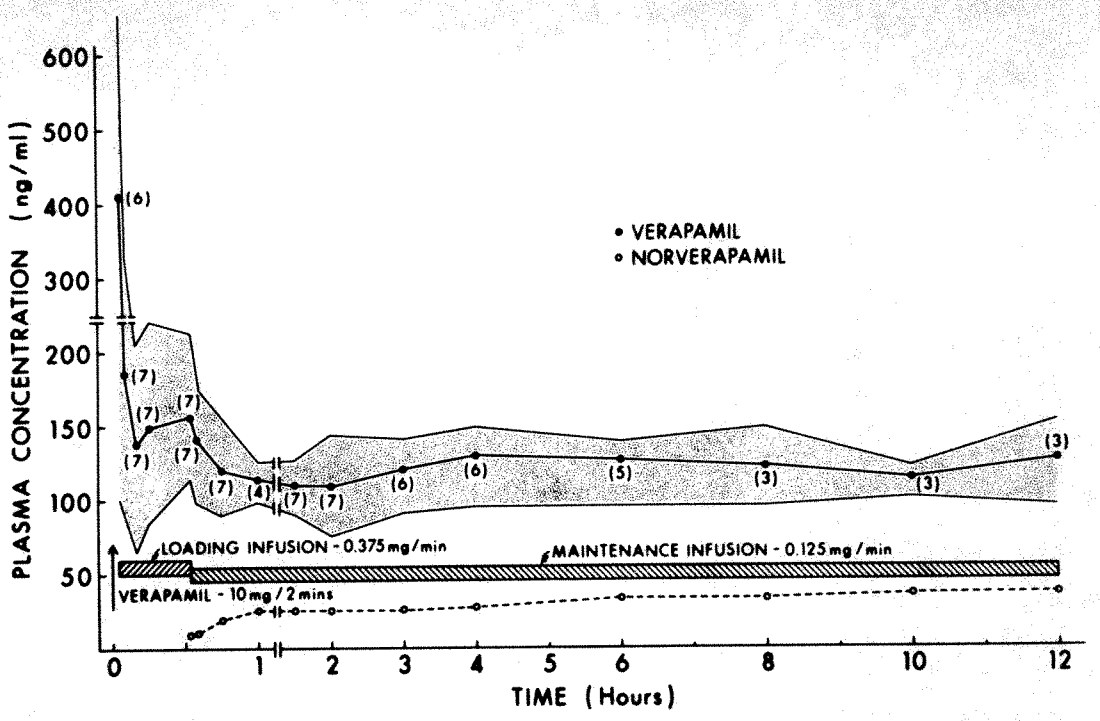

FIGURE 3. Mean and range of plasma verapamil concentration and mean norverapamil concentration are shown for the 7 patients who received the concentration-maintaining intravenous regimen. The number of patients for whom data are available at each time is shown in parentheses.

sions achieved a norverapamil level of 40, 41, and 36 ng/ml, respectively.

Blood pressure and heart rate: Brachial blood pressure and sinus cycle length decreased slightly in the first 3 minutes corresponding to the peak plasma verapamil concentration, but there was no sustained decrease in either. Mean systolic blood pressure decreased 10 ± 6 mm Hg from a control value of 118 mm Hg. Mean sinus cycle length decreased from 998 ± 33 ms (heart rate 60 beats/min) to 800 ± 94 ms (heart rate 75 beats/min). There was no significant decrease in blood pressure or cycle length at the second peak in plasma verapamil concentration (157 ng/ml) at the end of the rapid loading infusion.

P-R interval: The P-R interval was prolonged in all patients at 2 minutes (Fig. 4). Maximum negative dromotropic effect (138 ± 11% of control P-R interval) occurred between 5 and 45 minutes. Unlike the transient changes in blood pressure and sinus cycle length, P-R prolongation was sustained over the duration of the infusion (averaging 127% of control P-R interval) without apparent diminution and then slowly returned to normal in the 4 hours after termination of the infusion. Although first degree AV nodal block was common, no patient developed Wenckebach conduction or AV dissociation during the infusion.

Side effects: No significant side effects were noted during the sustained infusion of verapamil. One patient developed a mild headache 3 hours after the start of the infusion. The other six patients were without symptoms. No clinically significant hypotension, bradycardia, or arrhythmia occurred in any patient.

Discussion

We have described a concentration-maintaining method of administering verapamil. This 3 component regimen has the advantages of (1) rapid achievement

TABLE II Effects of Sustained Intravenous Verapamil Infusion in 7 Patients*

* Subjects 11 to 13 were normal volunteers; all others had paroxysmal supraventricular tachycardia.
† Steady state values represent observations at the end of the maintenance infusion. Values in parentheses represent the range of observations from the first hour to the end of the infusion.

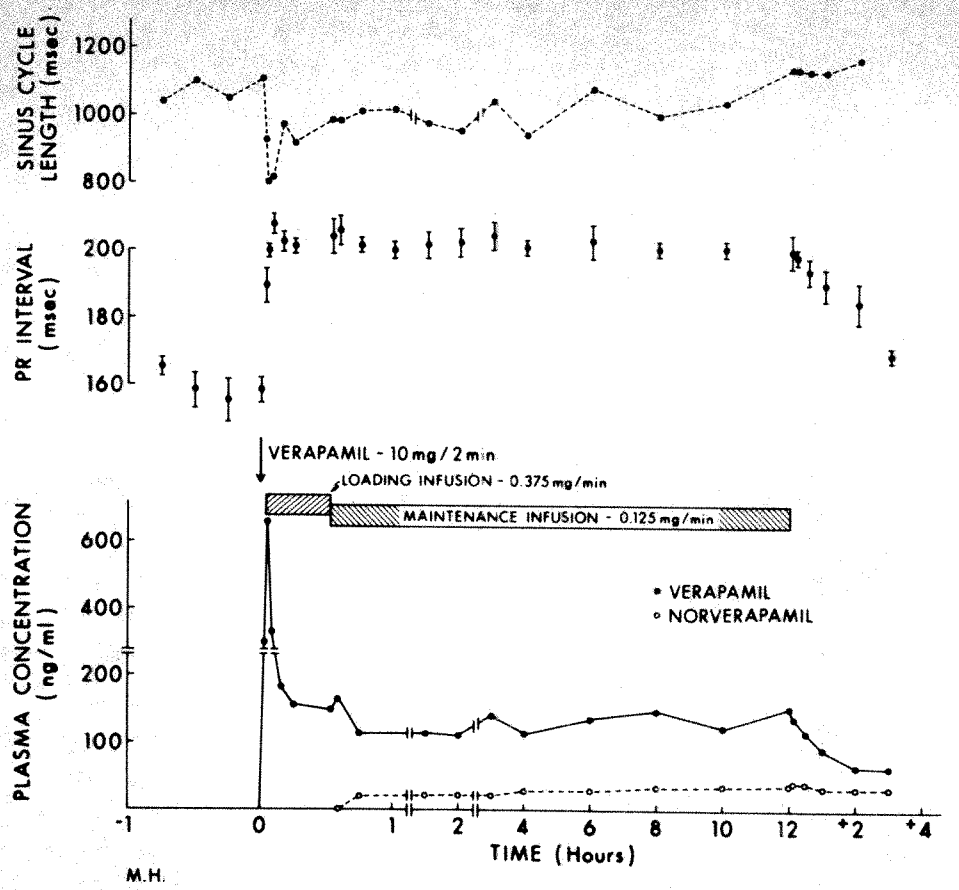

FIGURE 4. Patient 12. Plasma verapamil concentration, P-R interval, and sinus cycle length are shown for a patient who received the dose-maintaining regimen for 12 hours.

of therapeutic level, (2) elimination of a "dip" in concentration by the rapid loading infusion, (3) maintenance of steady state concentrations without significant accumulation (at least up to 12 hours), and (4) ease of administration. This regimen was tested in 7 patients and was found to be safe and to produce stable P-R interval prolongation for up to 12 hours.

Pharmacokinetics of verapamil: The final regimen selected and tested was based on pharmacokinetic variables determined after a single intravenous injection of verapamil. We elected to model the data from the 9 subjects who received a single injection to a 2 compartment model. This is in agreement with the observations of Dominic et al.,[18] who reported very similar values for the distribution and elimination phase half-lives as well as plasma clearance. Recently, Kates et al.[19] studied the disposition kinetic features of verapamil in patients with chronic atrial fibrillation and obtained similar values for clearance (13.3 ± 7.7 ml/min/kg) and for the volume of the central compartment (28.6 ± 24 liters). However, their pharmacokinetic data were interpreted as showing 3 exponential kinetics. This difference is probably related to the longer sampling time of Kates et al. Our data might similarly be solved by curves described by 3 exponents with a curve-fitting error comparable to the 2 exponent solution. We solved for 2 exponent terms to simplify the simulations by the method of separate exponentials. The success of our final regimen justifies this simplification.

Optimal plasma concentration: We constructed our infusion regimen to produce a plasma verapamil concentration of 150 ng/ml because this level has been shown to cause substantial slowing of AV nodal conduction.[11,20] Schwartz et al.[21] have shown that this plasma drug level produces stable slowing of the ventricular rate in patients with atrial fibrillation. However, other plasma concentrations are easily attainable. The method of separate exponentials predicts that other concentrations can be similarly achieved by changing the bolus, rapid loading infusion, and maintenance infusion doses by an amount in proportion to the desired final concentration. Thus, a final verapamil concentration of about 60 to 75 ng/ml can be achieved by a 5 mg bolus (10 mg × 0.5) over 2 minutes, a rapid loading infusion of 0.188 mg/min (0.375 mg × 0.5) for 30 minutes, and a maintenance infusion of 0.06 mg/min (0.125 × 0.5).

Verapamil metabolism and excretion: Verapamil undergoes hepatic metabolism before renal excretion. Only 3 to 4% of an oral dose is excreted as unmetabolized drug.[22] The major metabolic step involves N-deakylation with further metabolism by O-demethylation and subsequent conjugation. Norverapamil and other metabolites of verapamil may reach levels in the

plasma similar to or higher than those of verapamil after oral administration. In the present study, norverapamil was seen to accumulate during sustained intravenous infusion. However, norverapamil and the other major N-demethylated metabolites have insignificant effects on the AV node and hemodynamic effects significantly smaller than that of the parent drug.[23] Thus, there is no evidence that accumulation of metabolites during prolonged intravenous infusion would have untoward electrophysiologic or hemodynamic effects, although we have not directly evaluated this question. Verapamil clearance is decreased in patients with hepatic disease,[24] and the cautious use of verapamil by any route is appropriate in such patients or with the combined use of verapamil and cimetidine, which decreases hepatic blood flow.

Clinical implications: The benefit of verapamil in the therapy of supraventricular arrhythmias is related to its negative dromotropic effect on the AV node. The effect of a single intravenous dose of verapamil is transient and begins to decrease within 30 minutes, as shown in this and other[3,11,18] reports. This time course of dromotropic effect is similar to the effects of verapamil in slowing the ventricular rate in atrial fibrillation.[4,6,15] Our infusion regimen should be useful when a longer effect is desirable (for example, in the treatment of supraventricular tachycardia after cardiac surgery or myocardial infarction).

The blocking effect of verapamil on AV nodal conduction is due to its effect on the calcium-mediated slow response, an action unlike that of other antiarrhythmic agents. Thus, sustained intravenous verapamil infusion may be useful alone, or before or in combination with digoxin therapy, for the acute control of ventricular response where cardioversion is not indicated or not effective. Verapamil may have advantages over propranolol because it does not alter airway resistance and the negative inotropic action of verapamil is partly offset by a decrease in afterload. However, verapamil may produce a greater degree of hypotension in patients with atrial fibrillation than in patients with sinus rhythm[6] and may be deleterious in patients with severely reduced left ventricular function or with elevated left ventricular filling pressure.[25] Because of limited experience, sustained intravenous verapamil should be administered with caution in patients with left ventricular dysfunction. The concomitant use of intravenous verapamil and beta blockers is relatively contraindicated because of the reports of serious adverse reactions. Finally, this type of infusion may also be applicable in the treatment of hypertension, unstable angina, or variant angina because verapamil also causes dilatation of the coronary and systemic arteries. However, the hemodynamic effects of a sustained infusion of verapamil in these conditions has not yet been assessed.

Safety: The concentration-maintaining regimen that we designed to provide a verapamil plasma concentration of approximately 150 ng/ml can produce a sustained negative dromotropic effect comparable to the maximal effect seen after a single dose of 10 mg verapamil. During infusions up to 12 hours, no notable diminution of negative dromotropic effect was apparent. There was no evidence of significant tachyphalaxis or inhibition of the action of verapamil by metabolic alteration of the molecule. Moreover, the sustained plasma concentration was not associated with significant or sustained changes in blood pressure or sinus cycle length. We conclude that the described regimen will produce stable verapamil levels, sustained AV nodal slowing, and no significant toxicity.

Variability of Response to Beta Receptor Blockade for Angina Pectoris in Clinical Trials: A Study of Pindolol

WILLIAM E. HARSTON, MD and GOTTLIEB C. FRIESINGER, MD

In a randomized, controlled study we found a significant decrease in pressure-rate (double) product and an improvement in exercise tolerance in patients with angina pectoris treated with pindolol. However, when patients were observed in a long-term double-blind crossover study, pindolol treatment did not produce a significant improvement in angina pectoris or exercise tolerance over placebo. Patients treated with placebo had a gradual improvement in exercise tolerance, possibly because of the training effect of multiple treadmill tests and increased daily walking. The individual patient response to pindolol varied, with some patients showing clinical improvement and decreased double product with exercise and some having no clinical improvement despite a similar decrease in double product. Angina occurred at a lower double product with exercise, suggesting that beta receptor blockade adversely affected other variables of myocardial oxygen demand or decreased coronary blood supply. This study illustrates the difficulties with patient variability and study design that are encountered in studies of beta blocker agents for angina pectoris.

Pindolol is a nonselective beta receptor blocker that is 4 to 5 times as potent as propranolol on a milligram per milligram basis. Pindolol has intrinsic sympathomimetic activity and alters resting heart rate, left ventricular size,[1] and airway resistance[2] less than propranolol. We have studied the effects of pindolol on the frequency of angina attacks and on treadmill exercise tolerance in patients with stable angina pectoris. Previous studies using various types of protocols have produced conflicting results. To assess factors which may explain variability in results, we evaluated individual patient response and studied the same patients in a short-term comparison with placebo in parallel groups and in a longer double-blind crossover study.

Methods

Study patients: Fourteen patients with stable angina pectoris were studied. Two patients did not complete the study and are not included in the analysis. One patient discontinued the study because there were "too many treadmill tests." One patient was dropped from the study in the baseline period because of nonreproducible treadmill tolerance, ranging from 2 to 8 minutes on the same day with no obvious explanation. The average age was 52 years (range 35 to 68). There were 11 men and 1 woman. All patients had coronary artery disease documented by coronary arteriography with luminal stenosis of at least 70% in 1 or more coronary vessels. Each patient had stable angina pectoris for at least 3 months and had a positive treadmill test with a minimum of 1 mm of S-T segment depression accompanied by typical angina pectoris. No patient had hypertension, congestive heart failure, valvular heart disease, bradycardia less than 50 beats/min, or obstructive lung disease requiring treatment with bronchodilators, and none had had coronary bypass surgery or myocardial infarction in the previous 3 months. While no patient received other beta blocker agents, long-acting nitrates, or antihypertensive medication, any other medications the patients were chronically taking were not changed during the study period.

Study protocol (Fig. 1): The study protocol was a 15 week double-blind, randomized study in a crossover design. Weeks

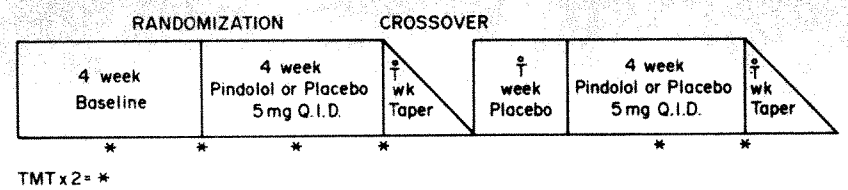

FIGURE 1. Diagram of study protocol. Treadmill tests (TMT) were done in duplicate 15 to 60 minutes apart at indicated intervals. wk = week.

1 to 4 were a baseline period in which the patients received placebo medication in a single-blind fashion. They were then randomized to sequence group 1 to 2. Sequence group 1 received placebo 4 times a day from weeks 5 through 8 and 5 mg of pindolol 4 times a day from weeks 11 to 14 in a double-blind design. Sequence group 2 received the treatments in reverse order. Weeks 9 and 15 were tapering off periods and week 10 was a crossover single-blind placebo period.

Variables evaluated: Each patient kept an angina diary and recorded the number and character of episodes of angina pectoris and the number of nitroglycerin tablets used. Daily activity was estimated by a pedometer recording the miles walked. At the end of weeks 2 and 4 in the baseline period and at the end of weeks 6, 8, 12, and 14 in the randomization periods, treadmill tests were done in duplicate 15 to 60 minutes apart. The treadmill tests were done in the postabsorptive state at the same time of day each visit 2 to 3 hours after a dose of study medication.

Treadmill tests were done according to the following protocol: Stage I, 1 mile/h at 0° elevation; stage II, 1 mile/h at 10° elevation; stage III, 1.5 miles/h at 10° elevation; and stage IV, 2 miles/h at 12° elevation. Each stage was continued for 3 minutes.

An electrocardiogram with 3 modified Frank vector leads and blood pressure were taken at rest and at the end of each stage and at the end-point of exercise. The electrocardiogram was monitored continuously by oscilloscope. Exercise was carried to the end-point of the patient's typical angina on each test, and the patients were asked to exercise to the same symptomatic point on each test. Each patient had a positive electrocardiographic response as defined by at least 1 mm flat or downsloping S-T depression for at least 0.08 second duration. The heart rate and systolic blood pressure product, an index of myocardial oxygen demand,[3] was calculated at rest and at the exact end-point of exercise.

Every 2 weeks a detailed cardiac history and physical examination were performed. Electrocardiogram, chest x-ray film, complete blood count, urinalysis, and routine blood chemistry determinations were done at entry and at the end of weeks 4, 9, and 15. Pindolol blood levels were drawn between the duplicate treadmill tests and analyzed by Sandoz Laboratories.

Statistical analysis: In comparing the 2 study groups, differences were calculated using an analysis of variance for a 2 period crossover study design. When evaluating a change from baseline for a single group, one-way analysis of covariance was used. Differences in baseline characteristics of groups A (good response) and B (poor response) were evaluated by the *t* test and chi-square test.

Results

Pindolol versus placebo: Table I summarizes the effects of pindolol on the clinical and exercise variables studied during the crossover study. The number of angina pectoris episodes and nitroglycerin tablets used per week and the amount of S-T depression at peak exercise on the treadmill were decreased more by pindolol than by placebo, but the differences were not statistically significant. The patients had a similar degree of improvement in exercise tolerance on the treadmill with both pindolol and placebo. The only difference between pindolol and placebo that was statistically significant was the reduction of rate-pressure product on the treadmill at peak exercise.

Types of response to pindolol: Figures 2 to 6 demonstrate the 3 types of response to pindolol shown by the individual patients. Four patients (Group A) had a good hemodynamic and clinical response to pindolol as demonstrated by Patient 14 in Figure 2. This group had a marked reduction in rate-pressure product at peak exercise and increased treadmill exercise tolerance over placebo (Fig. 3). Six patients (Group B) (Fig. 4) did not have improved exercise tolerance despite a reduction in rate-pressure product on exercise similar to that seen in Group A (illustrated by Patient 9 in Fig. 5). Two patients showed no difference in rate-pressure product at the end-point of exercise or in exercise tolerance between placebo and pindolol (Fig. 6).

Evaluation of baseline clinical factors in Group A (good response) and Group B patients showed no difference in the incidence of previous myocardial infarction, frequency of angina pectoris, baseline blood pressure, cardiothoracic ratio on chest x-ray, or whether they had placebo or pindolol in the first study period. However, Group A patients were older (59 years with

TABLE I Effects of Pindolol on Clinical and Exercise Variables

	Baseline	% Δ on Placebo	% Δ on Pindolol	% Differences in Pindolol and Placebo
AP/wk	5.2	−18	−32	14

Ex Tol on TM (s)	252.8	+11	+13	2
S-T dep on TM (mm)	1.9	−8	−14	6

* $p < 0.01$.

AP/wk = episodes of angina pectoris per week; DP on TM = double-product on treadmill test at end-point; Ex Tol on TM = duration of exercise tolerance on treadmill test; ST dep on TM = amount of S-T depression at end-point of exercise; TNG/wk = number of nitroglycerin tablets used per week; % Δ = percent change.

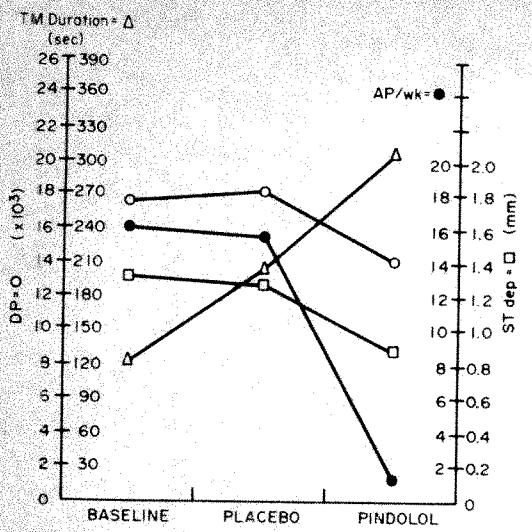

FIGURE 2. Patient 14. Results of measured variables at baseline, and in placebo and pindolol study periods. AP/wk = episodes of angina pectoris per week; DP = double-product at end-point of exercise; ST dep = S-T depression on electrocardiogram at end-point of exercise; TM Duration = treadmill duration (in seconds).

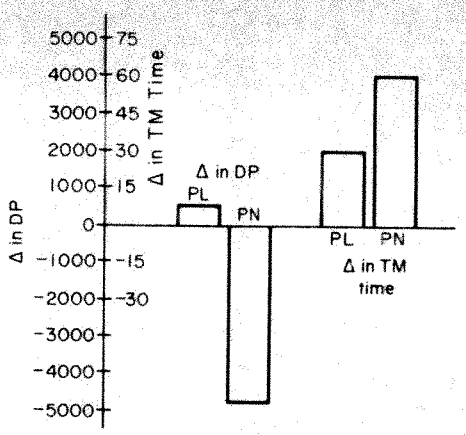

FIGURE 3. Improvement in double-product at peak exercise and exercise tolerance on the treadmill in Group A (4 patients with good clinical and treadmill response to pindolol). Δ in DP = change in double-product at the end-point of exercise from baseline; PL = placebo; PN = pindolol; Δ in TM time = change in exercise tolerance on treadmill from baseline (in seconds).

range of 64 to 67, versus 49 years with range of 40 to 61; $p < 0.02$), developed angina earlier on the baseline treadmill test (157.5 seconds, with range of 120 to 240, versus 250 seconds, with range of 195 to 390; $p < 0.05$), and had a longer duration of symptomatic ischemic heart disease (107 months, with range 56 to 240, versus 49 months, with range of 12 to 120; $p = 0.05$ to 0.10). In addition, Group A patients had a lower baseline standing heart rate (74 beats/min, with range of 60 to 85, versus 93 beats/min with range of 75 to 108; $p < 0.02$) and a slightly lower baseline supine heart rate (66 beats/min, with range of 52 to 75, versus 77 beats/min, with range of 64 to 90; $p = 0.05$ to 0.10). Angiography had been performed at varying periods of time before the study (3 months to 6 years), and the data on left ventricular function and severity of coronary disease were not considered valid for this analysis.

Sequence group 1 versus sequence group 2: Serial exercise tolerance was evaluated in the patients who were on placebo for the first 8 weeks of the study (4 weeks in the baseline period and 4 weeks in the first study period on placebo). Figure 7 shows a steady increase in exercise tolerance over the 8 week period while the patients were on placebo only. An alternate method of assessing the response to pindolol is to compare the baseline variables with those measured during the first

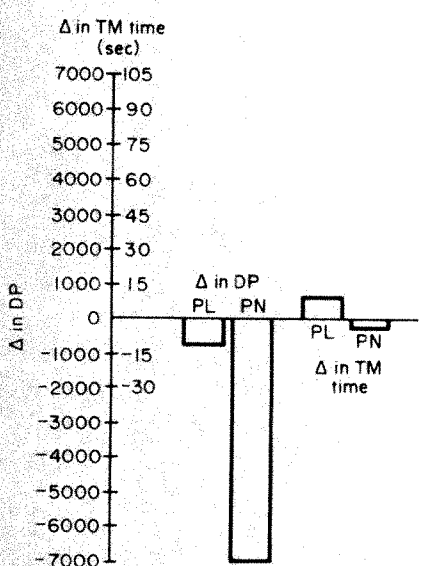

FIGURE 4. Change from baseline in double-product at the end-point of exercise and exercise tolerance on the treadmill in Group B (6 patients with a poor clinical and treadmill response despite reductions in double-product). Abbreviations as in Figure 3.

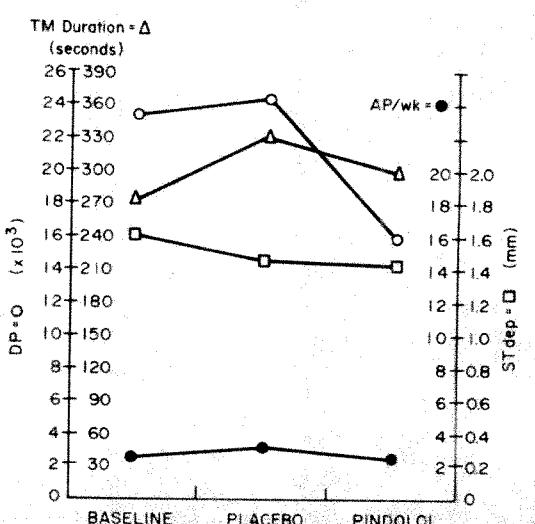

FIGURE 5. Patient 9. Results of measured variables at baseline, and in placebo and pindolol study periods. Abbreviations as in Figure 2.

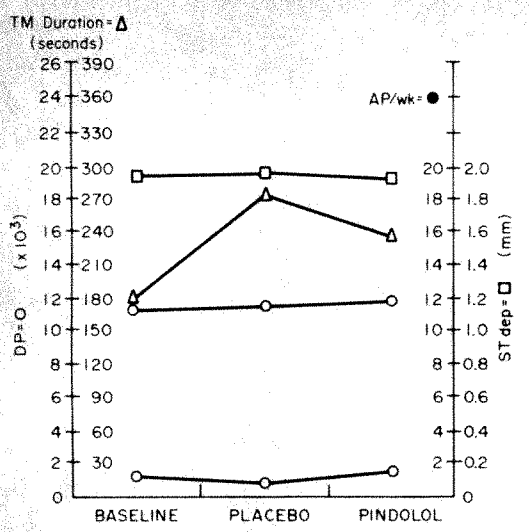

FIGURE 6. Patient 7. Results of measured variables at baseline, and in placebo and pindolol study periods. Abbreviations as in Figure 2.

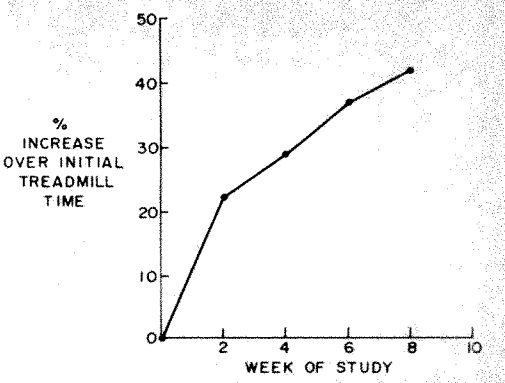

FIGURE 7. Sequence group 1. Percent increase in exercise tolerance on treadmill test in patients who were on placebo for first 8 weeks of study (4 weeks of stabilization and 4 weeks in first study period on placebo).

study period with each patient serving as his own control. There was no significant change in rate-pressure product at the end-point of exercise in the placebo period, but patients on pindolol had a 25% reduction ($p < 0.05$) in the double-product (Fig. 8). Similarly, there was a 16% increase ($p < 0.05$) in treadmill exercise tolerance in the patients on pindolol in the first study period (Fig. 9).

Pindolol blood level: The mean pindolol blood level was 22.3 ng/ml (range 5 to 37.5). Patients with a good clinical response (Group A) had blood levels (mean 23.1 ng/ml) that were similar to those of patients with poor clinical response (mean 24.6 ng/ml). One of the 2 patients who showed no reduction in double-product at peak exercise had the lowest drug level.

Daily walking: During the single-blind placebo stabilization period the patients walked an average of 1.31 miles/day, on pindolol 1.25 miles/day, and in the double-blind placebo period 1.47 miles/day, values which are not significantly different. During the baseline 4 week period patients walked an average of 1.31 miles/day, and during the last study period they walked an average of 1.46 miles/day.

Side effects: Pindolol did not produce any hematologic, hepatic, renal, or metabolic abnormality as evaluated by serial complete blood counts and routine blood chemistry values. Evaluation for multiple side effects revealed that only fatigue (5 patients versus 1 patient) and insomnia (4 patients versus 2 patients) occurred more often on pindolol than placebo.

Discussion

Comparison with previous studies (Table II): In previous studies the effect of pindolol on angina pectoris has been assessed using various protocols; 42 to 85% of patients had decreased angina pectoris on pindolol and there was 12 to 21% improvement in exercise tolerance on pindolol. In general, a greater improvement with the drug was seen in uncontrolled studies and in those in

* Fifty-six % of patients had a greater than 25% reduction in angina pectoris.
† Ten of 25 patients improved 50%; 7 of 25 patients showed no change or had decreased exercise tolerance.
A = double-blind crossover comparison with placebo; B = double-blind crossover comparison with propranolol and placebo; C = double-blind comparison with propranolol; D = double-blind comparison with placebo; E = not controlled; NR = not reported.

which the period of observation was shorter. Our results are remarkably similar to those of Arstila et al.,[4] and both studies used a double-blind crossover protocol with repeated evaluation of exercise tolerance. Slightly greater improvements in exercise tolerance by pindolol was demonstrated by Frishman et al.,[1] using a higher dose than that used by others. The inability to demonstrate an important clinical improvement in these studies probably is not related to the particular beta blocker agent being used since propranolol and pindolol were compared and produced quite similar results in 2 of the studies.[1,4]

Role of protocol design and interpretation of patient responses: Our study emphasizes the complexity involved in protocol design and interpretation of responses to beta blocker agents in stable angina pectoris. We can identify several factors that could be responsible for the varying responses of the patients in our study and that we assume may be confounding factors in any study similarly designed (Table III). The variable response to a given dosage and blood level of beta blocker drug in individual patients may reflect differences in sympathetic nervous system output at rest and with exercise or differences in individual absorption and metabolism. Ideally, the dosage for optimal beta receptor blockade should be titrated for each individual patient, using response to isoproterenol infusion or percentage reduction in heart rate with exercise as the end-point. However, this is virtually impossible to do in a placebo-controlled double-blind crossover study.

TABLE III Difficulties in Evaluating Beta-Blocking Agents in Angina Pectoris

I. Variables of study drug pharmacokinetics
  A. Variable response to same blood level
    1. Intrinsic sympathetic tone
    2. Receptor sensitivity to drug
  B. Variable blood level for same dose
    1. Absorption
    2. Distribution and metabolism
II. Hemodynamic variables in patients
  A. Left ventricular volume and pressure
  B. Coronary vasoreactivity
  C. Coronary flow distribution
III. Placebo effect: more prominent in short-term study with subjective evaluation
IV. Training effect: more prominent long-term study with exercise evaluation
V. Spontaneous change in underlying disease

Exercise tolerance after pindolol: The desired effect of beta blocker agents in ischemic heart disease is to reduce the myocardial oxygen consumption by decreasing heart rate and blood pressure, particularly with exercise. Pindolol produced a significant reduction in rate-pressure product on exercise in our study, and this was noted in 10 of 12 patients. Despite this favorable effect, 6 of the 10 patients (Group B) did not have an increase in exercise tolerance before developing angina. Our 4 patients with a good response (Group A) were older, had a longer duration of symptoms and had more limiting angina as demonstrated by poor treadmill exercise tolerance at baseline. Perhaps a similar degree of beta blockade produced a greater clinical response in such patients. The 6 patients with a poor response had a higher resting heart rate at baseline. This could have indicated higher baseline sympathetic tone and might require a higher dose of beta blocker agent.

The occurrence of angina at a lower rate-pressure product on a beta blocker agent was also noted by Arstila et al.,[4] who postulated that this could be due to an increase in myocardial oxygen consumption through increased left ventricular volume and wall stress, or a decreased supply either in overall coronary flow or a change in distribution of flow. Frishman et al.[1] showed a significant increase in left ventricular diastolic volume by both pindolol and propranolol on echocardiographic evaluation. Even though our patients were highly selected and all had well-documented coronary artery disease, angina pectoris, ischemic electrocardiographic response to treadmill testing, and no symptoms of congestive heart failure, their left ventricular volumes and pressures (estimated from previous cardiac catheterization) varied widely. It is possible that a beta blocker agent could produce a variable increase in left ventricular volume, thus increasing wall stress and

countering the reduction in myocardial oxygen demand through a reduced double-product. This could explain why some patients did not have an increase in exercise tolerance despite similar reductions in double-product. Alternatively, since coronary vasoreactivity to beta blockers may differ in individual patients,[10] a favorable reduction in myocardial oxygen consumption could be countered by decreased coronary supply to a variable degree. In addition to the potential to reduce total coronary flow by reducing beta-adrenergic vasodilatory influences, increases in wall tension and extravascular compressive force could cause a redistribution in coronary blood flow and produce relative subendocardial ischemia.

Placebo effect and other factors affecting angina: This study illustrates the importance of the placebo effect in the treatment of angina pectoris. Other studies[11,12] have found the incidence of angina pectoris to show a continued reduction for 8 to 11 weeks on placebo before leveling off. To negate this effect, drug studies in patients with angina pectoris should be placebo-controlled and done in a crossover design, and objective evaluation should be done with treadmill testing. Using this type of protocol, our study and that of Arstila et al.[4] did not show as much clinical improvement as other reported studies (Table II). However, repeat treadmill tests during this longer type study could produce a training effect. This could occur because of the extra exercise of the treadmill tests themselves, but it is more likely that the patients learn that they can safely exercise even to the point of angina and thus increase their daily activities. Our pedometer data suggest that this is a possibility, but we have no control data; that is, patients did not wear the pedometer before commencing the study. Finally, in a long-term study of angina pectoris, changes in underlying disease could occur through either progression or regression of atherosclerosis, changes in collateral circulation, or compensatory hypertrophy. However, significant changes should be unlikely in studies that are less than several months in duration.

Antiarrhythmic, Antifibrillatory, and Hemodynamic Actions of Bethanidine Sulfate: An Orally Effective Analog of Bretylium For Suppression of Ventricular Tachyarrhythmias

MARVIN B. BACANER, MD and DAVID G. BENDITT, MD

Bethanidine sulfate is a chemical and pharmacologic analog of bretylium tosylate that has virtually identical antifibrillatory and inotropic actions on the heart. Bretylium is the only drug approved by the Food and Drug Administration specifically for the "prophylaxis and treatment of ventricular fibrillation." Unlike bretylium, which is poorly absorbed from the gut and limited to parenteral use, oral bethanidine is absorbed rapidly. Bethanidine was given to 23 patients with recurrent multiple drug refractory ventricular tachycardia and fibrillation. Eighteen patients (78%) had complete suppression of spontaneous or electrophysiologically inducible tachyarrhythmias; 3 were improved and 2 had no benefit. In 6 of a 9 patient subgroup studied by programmed electrophysiologic drug testing, bethanidine completely prevented previously inducible ventricular tachyarrhythmias at the maximal stimulus tested (including 4 extrastimuli and burst-pacing at 10 times threshold). Cardiac output measured in 6 patients 1 to 2 hours after bethanidine was increased in 4, unchanged in 2, and decreased in 1. Ten patients on long-term therapy with bethanidine and protriptylene (to prevent orthostatic hypotension) have been free of arrhythmias from 2 to 26 (average 13) months.

Ventricular fibrillation (VF) is the major cause of death in our society.[1] Many cardiac patients at high risk of sudden death might be protected by prophylactic treatment with an orally effective drug that prevented VF.[2,3] At present, bretylium tosylate is the only drug approved by the Food and Drug Administration for the "prophylaxis and treatment of VF."[4] Bethanidine sulfate is a closely related chemical analog of bretylium tosylate which has virtually identical pharmacologic actions on the ventricle.[5–9] Unlike bretylium, which is poorly absorbed from the gut, oral bethanidine is absorbed rapidly.[5,10,11]

Bretylium tosylate suppresses and prevents VF and induces chemical ventricular defibrillation in experimental animals[6,12–23] and in man.[6,14,24–39] It is limited, however, to parenteral use because therapeutic levels are difficult to achieve and maintain by oral administration alone.[11,39] Because of disappointing therapeutic results in patients treated with oral bretylium to prevent out-of-hospital VF,[38,39] it was decided to reinvestigate the efficacy of bethanidine sulfate in the suppression of life-threatening ventricular arrhythmias in man.[5,40]

During our original studies in the early 1960s on the effect of sympatholytic drugs on VF, it was observed that bethanidine and bretylium had virtually identical antifibrillatory and inotropic actions on the canine ventricle.[5–8,41] More recent studies confirmed that bethanidine increased the VF threshold 150% in the normal canine heart and 327% in the infarcted heart and resulted in nonsustained VF.[7,8]

In pilot human trials bethanidine, like bretylium, also was effective in suppressing arrhythmias and VF.[5,40] Similarly, both drugs induced orthostatic hypotension.[9,11,24,28,40] In deciding in 1965 which drug to test in major clinical studies, bretylium was chosen because tolerance to orthostatic hypotension developed quickly, allowing patients to be ambulated.[24,28,31,39,42] In contrast, tolerance to orthostatic hypotension almost never developed during bethanidine treatment ([43] and unpublished observations). Thus, persistent orthostatic hypotension precluded the successful use of bethanidine as an antifibrillatory drug in ambulatory patients and studies were abandoned.

It has since been learned that orthostatic hypotension induced by both bretylium and bethanidine can be effectively antagonized by a variety of drugs, particularly tricyclic antidepressants such as protriptyline and desipramine which are believed to block the norepinephrine pump.[43,44] If bethanidine can be used in ambulatory patients by combined therapy with a tricyclic, this could be an effective oral means of preventing out-of-hospital VF.[40]

This report describes effects of bethanidine used together with protriptyline in 23 consecutive patients with current drug refractory ventricular tachycardia (VT) and VF.

Methods

Patient selection: Twenty-three consecutive patients with repetitive unsustained VT (runs of 6 to 99 ventricular ectopic beats) or sustained VT (more than 100 beats) were treated with bethanidine because they could not be controlled by other antiarrhythmic drug regimes. Sixteen patients also had from 1 to 20 episodes of VF. The patients had a variety of heart diseases, and 16 patients had congestive heart failure when bethanidine was started.

All patients were accepted if (1) they had multiple episodes of out-of-hospital life-threatening VT and/or at least 1 episode of primary VF, (2) they could take oral medication, and (3) they gave informed consent. All other antiarrhythmic drugs were discontinued. In 10 patients, tachyarrhythmias were initially treated successfully with betylium before a trial of bethanidine. In each patient, bretylium was discontinued and treatment with bethanidine was not started until tachyarrhythmias reappeared to make certain that acute efficacy of bethanidine could be assessed clearly from the time course of the response.

Patients received a loading dose of bethanidine ranging from 3 to 30 mg/kg and a maintenance dose of 10 to 40 mg/kg per day. All patients also received protriptyline, 15 to 120 mg/day, in divided doses to antagonize orthostatic hypotension.

Specific drug testing by programmed electrophysiologic stimulation: Nine patients had cardiac catheterization to place electrodes for programmed electrophysiologic study. Each patient had had 1 or more cardiac arrests outside the hospital. In the initial electrophysiologic study, quadrapole catheter electrodes were positioned in the right atrium, His bundle, and right ventricle for recording, pacing, and stimulation. An arterial line was placed in 7 patients to assess the effect of bethanidine on cardiac output (measured by dye dilution).

The test routine was designed to induce VT by delivering from 1 to 4 programmed ventricular extrastimuli (at 2 times threshold current) to the right ventricle while it was paced at a cycle length range of 400 to 500 ms. A rest interval of at least 10 sinus beats was taken before introduction of extrastimuli. The program systematically added and shifted the extrastimuli in the cardiac cycle and varied the coupling interval. When VT could not be induced by 4 sequential extrastimuli, ventricular burst-pacing (6 to 10 beats) was used. Starting with a cycle length of 400 ms, it was progressively shortened to 230 ms or until 1-to-1 ventricular capture was no longer possible. The end point of the study was the induction of reproducible episodes of either unsustained or sustained VT or bursts of VF or flutter which were terminated by rapid right ventricular pacing or electrical cardioversion.

After VT was reproducibly induced during the control study, the test drug was administered and the procedure repeated. The test drugs used were bethanidine, quinidine, procainamide, and disopyramide. Starting with patient 5 (Table I), when bethanidine was found to prevent previously inducible tachyarrhythmia with 4 extrastimuli or burst-pacing at 2 times threshold (approximately 1 mA), the current strength was increased to 10 times threshold (8 mA, the maximal output of the current generator). The stimulus routine was then repeated as the ultimate test of bethanidine-induced resistance to initiation of ventricular tachyarrhythmia. The test dose of bethanidine ranged from 16 to 30 mg/kg. It was given with 10 to 15 mg of protriptyline to test the interaction with bethanidine. Cardiac output was measured in triplicate by indicator dilution technique before and again 1 to 2 hours after the oral loading dose of bethanidine.

TABLE I Programmed Electrophysiologic Drug Testing

	Extrastimuli to Induce VT/VF		Cardiac Output (liters/min)	
Case	Control	Bethanidine	Control	Bethanidine
1	2	NI	3.90	5.40
2	3	NI	4.50	5.15
3	3	NI	6.90	7.30
4	3	4	3.92	2.62
5	3	NI (10 t)	4.53	5.2
6	SVT	NI (10 t)	. . .	. . .
7	2	3	4.65	4.76
8	2	NI (10 t)	4.50	4.40
9	3	2	. . .	. . .

NI = not inducible at 2 times threshold; SVT = spontaneous ventricular tachycardia; 10 t = 10 times threshold.

Initially 16 mg/kg of bethanidine with 10 mg of protriptyline were given and tested 1 to 1.5 hours after administration. This was followed by a second 8 mg/kg dose tested 45 minutes later. The initial loading dose of bethanidine was increased to 20 mg/kg given with 15 mg of protriptyline. To exclude dose dependence, an additional dose of 10 mg/kg bethanidine was given if the initial dose did not completely prevent inducible arrhythmia with 4 extrastimuli or burst-pacing.

The order in which test drugs were given was varied randomly and 3 to 4 days were allowed for the previous drug to be eliminated. The doses of quinidine, procainamide, and disopyramide used were the highest doses considered safe as judged by changes in conduction and checked by measuring blood levels drawn immediately after the test procedure. Blood levels of bethanidine were measured in serial blood samples drawn during electrophysiologic drug studies.

Results

The patients included 16 men and 7 women aged 21 to 75 years (mean 53). Before treatment with bethanidine, all patients had recurrent episodes of ventricular tachyarrhythmias lasting 3 days to 1.5 years and 16 patients had episodes of VF. These tachyarrhythmias had not been suppressed by aggressive treatment with 3 or more antiarrhythmic drugs singly or in various combinations before bethanidine was administered. Bethanidine suppressed existing repetitive or electrically inducible VT and VF in 18 (78%) of 23 patients, none of whom had further tachyarrhythmia while on bethanidine. Ten patients in whom tachyarrhythmias had been previously suppressed with bretylium had recurrences 8 hours to 6 days after bretylium was discontinued. In each patient, bethanidine suppressed the recurring tachyarrhythmia as early as 6 minutes or as late as 5 hours after ingestion (Fig. 1 and 2). Delay greater than 2 hours in the onset of action and ultimate efficacy appeared dose-dependent in patients who received a starting dose less than 20 mg/kg. In 3 other patients with recurrent episodes of VT, tachyarrhythmias were temporarily suppressed or became more difficult to induce during programmed electrophysiologic drug testing. In 3 patients, bethanidine was effective but was discontinued because of side effects. In

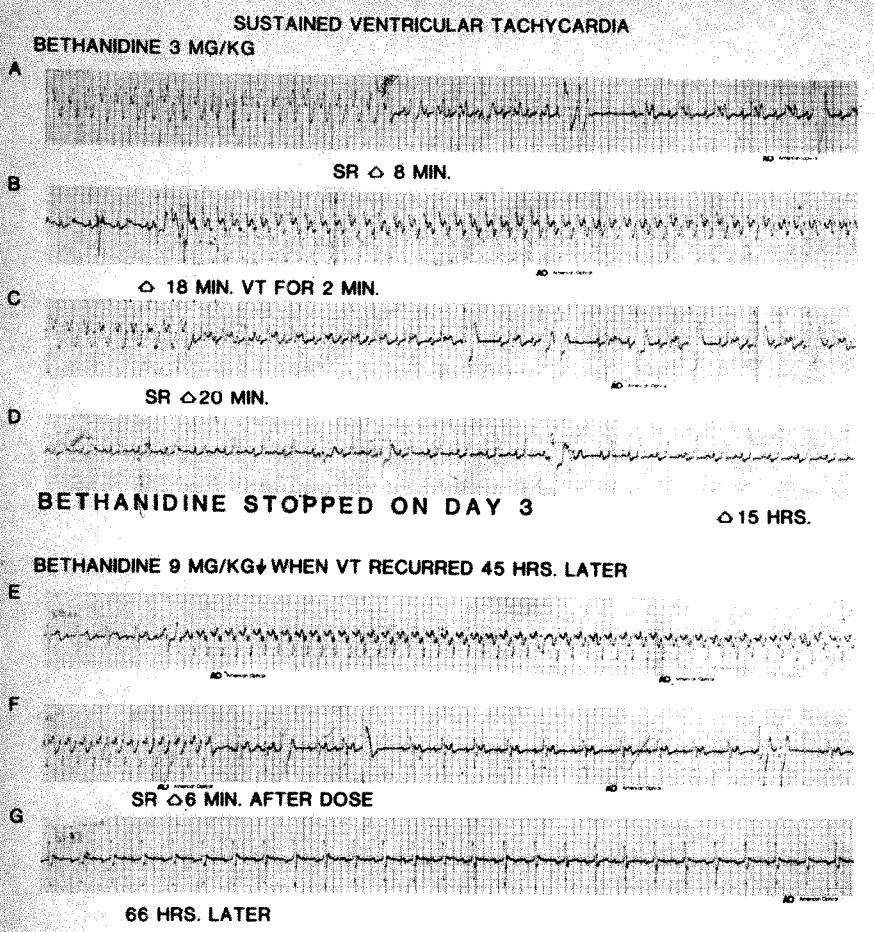

FIGURE 1. Record of 1 patient showing rapid conversion of sustained VT to sinus rhythm (SR) by oral bethanidine on 2 occasions (**strips A** and **C** and then again on **strip F**).

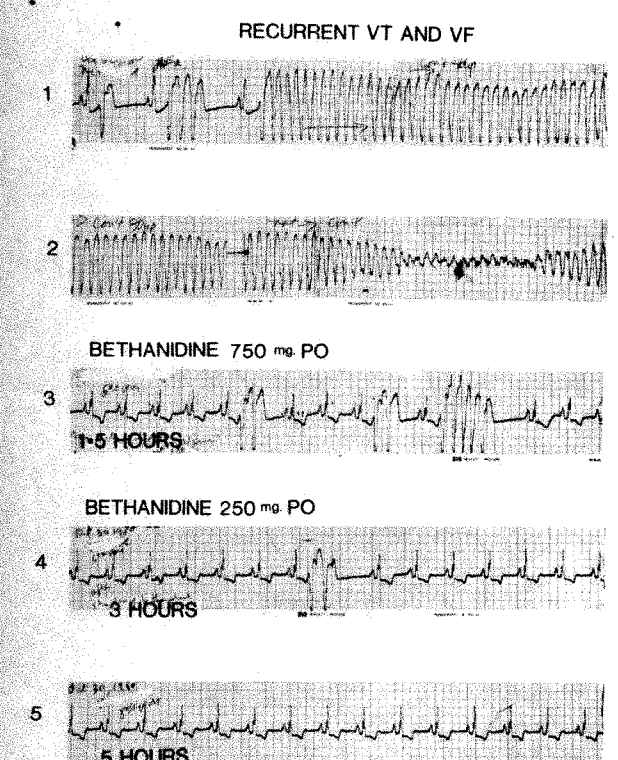

FIGURE 2. Record of a patient showing suppression of VT and VF by oral bethanidine. PO = by mouth.

2 patients bethanidine was of no value. Two patients died while receiving bethanidine.

Programmed electrophysiologic drug testing: In the control state 8 of the 9 patients had VT and/or VF-flutter inducible with 1, 2, or 3 programmed extrastimuli; the other patient was having frequent spontaneous episodes of unsustained VT during the control period and was too unstable for electrical induction to establish a control threshold.

Effect on stimulus tolerance: Bethanidine treatment (16 to 30 mg/kg) completely protected 6 of the 9 patients from inducible arrhythmia at the maximal stimulus intensity tested (Table I). Except for Patient 2 (Table I) who was protected by both bethanidine and quinidine, no other patient in this group received a drug other than bethanidine which prevented inducible arrhythmias at maximal stimulation. Three patients, who could not be induced by the usual provocation at 2 times threshold current after bethanidine, tolerated 4 extrastimuli and burst-pacing at a current 10 times above threshold (8 mA) without the induction of arrhythmias. Two other patients (Patients 4 and 8) were partly improved by bethanidine in that resistance to induction of VT increased from 3 to 4 extrastimuli, and from 2 to 3 extrastimuli. One patient had no benefit from any drug tested; all antiarrhythmic drugs appeared to make him worse.

Blood levels: After a 16 mg/kg dose, serial blood samples in 3 patients indicated that the bethanidine blood level rises rapidly to 0.18 to 0.25 μg/ml within 15 minutes. Bethanidine blood levels continued to rise to levels of 0.74 to 1.51 μm/ml 1.5 to 2 hours after ingestion where maximal protection against inducible arrhythmias was observed.

Effect of other antiarrhythmic drugs on stimulus tolerance: The effect of quinidine at doses up to 6 μg/ml blood levels was assessed in 4 patients, but only 1 patient had any benefit. In 2 patients VT became more easily inducible on quinidine than in the control state. Two patients who were well protected by bethanidine alone had no benefit from bethanidine when it was given immediately after quinidine testing.

Procainamide in doses up to 16.7 μg/ml and 10.4 μg/ml NAPA was studied in 5 patients, but none were protected at the maximal stimulus tested. One patient's tolerance increased from 3 to 4 extrastimuli before VT was induced. After administration of bethanidine, VT could not be induced in this patient with 4 extrastimuli or burst-pacing at 10 times threshold. Disopyramide was of no value in 2 patients tested. It was not tested in other patients because it was contraindicated by severe congestive heart failure.

Effect on cardiac hemodynamics: One to 2 hours after oral bethanidine, cardiac output and stroke volume increased in 4 patients, remained essentially unchanged in 2 patients, and decreased in 1 patient (Table I). Heart rate and supine blood pressure were essentially unchanged from control values.

Outpatient experience: Fifteen patients were discharged on doses of bethanidine ranging from 10 to 40 mg/kg per day and protriptyline 15 to 80 mg/day in divided doses, and 13 patients (86%) had no further episodes of VT or VF while on bethanidine. Although effective in suppressing ventricular tachyarrhythmia, bethanidine was discontinued in 3 patients: in 1 because of pregnancy, 1 because of anxiety over taking an investigational drug, and 1 because of persistent orthostatic hypotension. Two patients on bethanidine died after discharge from the hospital.

Long-term maintenance on bethanidine: Ten patients have been maintained on bethanidine from 2 to 26 months (average 13) with complete suppression of tachyarrhythmia. Periodic Holter monitor studies in all patients every 2 to 3 months have shown single ventricular ectopic beats and pairs but no triples or runs of VT, except as described later. When ectopic pairs were noted on the Holter record, the dose of bethanidine was increased by 50 to 100 mg/dose and adjusted to subsequent Holter findings. After 14 months on bethanidine 1 patient reported a brief episode of symptoms, which may have been a run of VT that disappeared 3 to 4 minutes after he took 700 mg of bethanidine. Except for that instance he has been free of symptoms for 26 months and has returned to full-time work for the past 22 months. One other patient had a single episode of VT 3 months after discharge, at which time the serum potassium level was 2.7 mEq/liter. Stable sinus rhythm was restored as soon as potassium was administered. Bethanidine treatment with potassium supplement was continued, and she has remained free of arrhythmia for the past 11.5 months.

Mortality: Four patients have died while on bethanidine, 2 while in the hospital. Despite satisfactory suppression of the arrhythmia, 1 died from a pulmonary embolus, and another from acute myocardial infarction with refractory intermittent VT not responsive to any drug including bethanidine. Both patients who died outside the hospital had severe congestive heart failure.

Discussion

Bethanidine was safe and effective in acutely suppressing both spontaneous and electrophysiologically inducible ventricular tachyarrhythmias in 78% of the 23 patients treated. Ten patients on long-term maintenance treatment with bethanidine and protriptyline have been free of tachyarrhythmia for 2 to 26 months (mean 13). All 23 patients had recurrent VT and 16 had 1 or more out-of-hospital cardiac arrests. These tachyarrhythmias had been previously refractory to at least 3 other antiarrhythmic drugs used singly or in various combinations. Sixteen patients had moderate to severe congestive heart failure.

Another potentially beneficial effect of bethanidine was its positive inotropic action,[8] which was manifested by an increase in cardiac output in two thirds of the patients tested. Because increased cardiac output was observed 1 to 2 hours after administration of bethanidine, it was unlikely to be solely an effect of catecholamine release, which would probably be much shorter in duration. The long-term effects on cardiac performance have not been assessed, but the patients maintained on bethanidine have shown no adverse hemodynamic effects.

Test of efficacy: The test of efficacy relied on each patient as his own control. Great care was taken to establish (1) that tachyarrhythmias were indeed repetitive and refractory to other drugs, and (2) that efficacy could be judged by an appropriate interval between the time bethanidine was administered and the time that sustained elimination of the arrhythmia occurred.

Electrophysiologic drug testing by programmed ventricular stimulation is widely accepted as a reproducible semiquantitative method of evaluating and matching the efficacy of a drug and its dose to a patient's specific arrhythmogenic cardiac disorder.[46-52] In our 9 patients undergoing programmed drug study, this was an acceptable controlled evaluation. In the other 14 patients the criteria for efficacy were less rigorous because evaluation of data was based on rhythm history and evidence of acute suppression. In each request for treatment with bethanidine, an experienced cardiologist indicated that either (1) the arrhythmias were persistent, lasting at least 3 days, (2) all other antiarrhythmic drugs tested had failed clinically, or (3) the arrhythmia was successfully suppressed with bretylium but an oral drug was also needed to send the patient home. In 10 patients in whom the arrhythmia was initially suppressed with bretylium, it was discon-

tinued and bethanidine was not administered until the tachyarrhythmia returned.

Dose-dependent efficacy: It also was apparent that the onset of action was dose-dependent (Fig. 1). With a low dose of bethanidine (3 mg/kg), initial conversion to sinus rhythm began in 8 minutes after ingestion and lasted 10 minutes, but was then interrupted on the 18th minute by another 2 minute burst of VT before definitive reversion to sinus rhythm occurred on the 20th minute after sufficient bethanidine had been absorbed. After 3 days bethanidine was stopped and 45 hours later VT returned. When a larger loading dose (9 mg/kg) was given for the second episode of VT, definitive conversion to sinus rhythm occurred after 6 minutes. Such a rapid response suggests that the therapeutic level of bethanidine needed to suppress VT had fallen to only slightly below the antiarrhythmic threshold concentration. Only 6 minutes were needed to absorb the small amount of bethanidine needed to bring the drug back to a therapeutic level.

The dose-dependent action of bethanidine was also demonstrable during programmed electrophysiologic drug testing when bethanidine was tested after administration of each additional dose and stimulus tolerance was observed to increase with each dose up to 30 mg/kg.

Electrophysiologic drug testing: The complete prevention of inducible arrhythmias in 6 of 9 patients and the partial protection in 2 others after bethanidine intake was a very favorable frequency of success for a single drug. Moreover, bethanidine was the only tested drug that was significantly effective in any patient except for quinidine in 1 patient. By comparison, reports on many antiarrhythmic drugs from centers using electrophysiotopic drug testing indicate that in only 30 to 50% of patients tested did any drug or combination of drugs prevent inducible tachyarrhythmia.[46–52]

The maximal number of extrastimuli used was progressively increased during the course of the study. When patients tolerated 3 extrastimuli and burst-pacing, 4 extrastimuli were tested. In later studies, when patients on bethanidine tolerated 4 extrastimuli and burst-pacing at 2 times threshold, the current was increased to the maximal current output of the system (8 mA), which was approximately 10 times threshold, and the test protocol was repeated. Of 3 patients subjected to this extreme provocation, none had inducible arrhythmia while on bethanidine, although arrhythmias were readily inducible in all in the control state or on other drugs. This was by far the most aggressive attempt to induce arrthythmias by programmed ventricular stimulation reported from any laboratory.[46–52]

It is true that the superthreshold stimulation was much greater than any provocation that can occur clinically short of electrocution. Nevertheless, bethanidine demonstrated a protective action that was not obtainable with any other antiarrhythmic drug tested. It remains to be established that such a test is clinically meaningful.

One potential value of superthreshold stimulation is that it may provide a basis for distinguishing between drugs when several drugs prevent inducible arrhythmias at stimulus levels usually employed.[46–52] In 1 patient, both quinidine and bethanidine prevented inducible arrhythmias with 4 extrastimuli or burst-pacing at twice threshold. This patient, therefore, was discharged on quinidine because it was prudent to use an approved drug rather than an investigational drug when both appeared equal in ability to prevent induced arrhythmias. The patient died suddenly 6 months after discharge. If an additional superthreshold challenge had shown that bethanidine was more protective than quinidine at 10 times threshold, the patient might have been discharged on bethanidine. Of the patients in whom bethanidine has been shown effective by electrophysiologic drug testing, none has died, whereas 2 patients discharged on other drugs died suddenly.

Drug antagonism: Bethanidine should not be given together with quinidine, which was found to antagonize its therapeutic effect in 2 patients. Similar antagonism to bretylium efficacy also has been reported with quinidine as well as procainamide and other cardiodepressant antiarrhythmic drugs.[6,24,31,53] Concomitant administration of bethanidine with other antiarrhythmic drugs or tricyclic antidepressants other than protriptyline probably should be avoided until compatibility can be demonstrated.

Pharmacologic side effects: The only significant side effect of bethanidine is orthostatic hypotension. No acute toxicity occurs in the dogs at 300 mg/kg, which is 10 times the highest therapeutic dose.[43] No chronic toxicity has been observed in monkeys or mice at 50 mg/kg per day.[43] Bethanidine induces postganglionic sympathetic blockade by blocking catecholamine release from sympathetic nerve endings, and the resulting chemical sympathectomy reduces peripheral resistance.[9] Blood pressure in the supine position may decrease but usually changes little because the positive inotropic effect usually increases cardiac output sufficiently to compensate for the decrease in peripheral resistance.[8] Orthostatic hypotension, however, is a regular pharmacologic side effect of bethanidine which is aggravated by inhibition of baroreceptor responses.[43]

Management of orthostatic hypotension: Concomitant administration of protriptyline was effective in antagonizing bethanidine-induced orthostatic hypotension in doses much lower than those used for antidepressant therapy. Protriptyline did not interfere with the antiarrhythmic-antifibrillatory actions of bethanidine as the arrhythmias remained suppressed after protriptyline was added. Indeed, some tricyclic antidepressants have been reported to increase the VF threshold.[54] Moreover, in our recent animal experiments, protriptyline alone increased the VF threshold and also had a synergistic interaction with bethanidine so that a combination of the 2 drugs increased the VF threshold higher than did either drug alone (unpublished observations).

The first 13 patients did not receive protriptyline until it was clear that their arrhythmias were suppressed by bethanidine. The dose of protriptyline needed to raise the VF threshold (5 mg/kg) was much higher than even the highest dose used to antagonize the orthostatic

hypotension, indicating that protriptyline itself does not account for the antiarrhythmic effect observed in patients on both drugs. Nortriptyline did not raise the VF threshold of the canine heart and appeared to antagonize bethanidine action (unpublished observations).

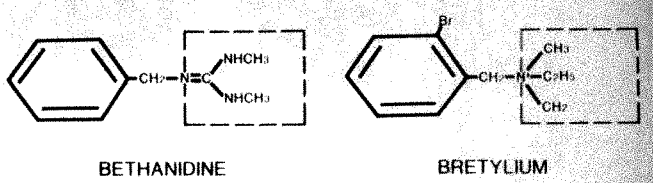
Despite effective suppression of arrhythmias, bethanidine was discontinued in 2 patients because of persistent orthostatic hypotension. One patient had severe congestive heart failure. He had an abnormally low resting cardiac output which was lowered still further by bethanidine; he was the only patient in which this occurred. Persistent orthostatic hypotension probably reflected a limited cardiac reserve, so that the decrease in peripheral resistance was not compensated by the positive inotropic action of bethanidine. In the second patient, bethanidine was discontinued because orthostatic hypotension persisted with 40 mg/day of protriptyline and at that time we were not yet using higher doses of protriptyline.

Bethanidine dosage: We started cautiously at the low end of the bethanidine dose (3 mg/kg) that was found to increase the VF threshold in the dog.[8] It became apparent in our first patient (Fig. 1) that this dose was marginal, so we quickly increased the loading dose. In the patients studied by electrophysiologic drug testing, it became apparent that 20 mg/kg followed by another 10 mg/kg, if needed, was generally effective in preventing inducible arrhythmia with bethanidine.

Guide to maintenance therapy: After the 20 mg/kg loading dose, maintenance therapy was started using 5 to 8 mg/kg bethanidine 4 times daily together with 30 to 80 mg/day of protriptyline in divided doses. Ambulation began with dangling the legs at the bedside and walking only with assistance. If symptoms of orthostasis persisted, the protriptyline dose was increased progressively until all symptoms (dizziness or syncope) were eliminated. One patient received 120 mg/day for 1 day, but this dose should not be continued for more than 1 day because of the possibility of an anticholinergic reaction. It is safer to take more time at doses of 60 to 80 mg/day. Patients were instructed to change to the upright position slowly to allow for slow adaptation to position changes and to take an extra 5 mg of protriptyline as necessary in addition to the regular doses if they became lightheaded after discharge. If protriptyline (15 mg TID) is given for 3 days before starting bethanidine the patients can be ambulated immediately (Robins AH, unpublished observations).

Bethanidine dosage was adjusted upward by 50 to 100 mg per dose or per alternate dose if pairs or triple ventricular extra beats were observed. No attempt was made to suppress single ventricular extra beats (even if frequent) or even short episodes of bigeminal rhythm. Long episodes may respond to an increase in dose, but the objective of treatment should be to prevent VT and VF by increasing the VF threshold so that premature beats are rendered harmless.

The antihypotensive action of protriptyline began about 4 hours after administration but took many hours or days to achieve maximal effect. Protriptyline tends to have cumulative effects, so after 4 to 6 weeks the protriptyline dose was reduced. This was done by reducing the dose by 5 mg/24 hours. After the initial adjustment period, most patients got along well on 15 to 30 mg/day of protriptyline. Impotence has occasionally been a bothersome side effect of sympathetic blockade but was eliminated by increasing the dose of protriptyline. One patient had persistent nausea which caused anorexia. Despite a good therapeutic response, bethanidine was discontinued and the nausea disappeared.



BETHANIDINE BRETYLIUM

FIGURE 3. Structural formula of bethanidine and bretylium. The **dashed lines** show the substitution of dimethylguanidine for quaternary ammonium removing the fixed positive charge that interferes with oral absorption of bretylium.

Comparison of bethanidine and bretylium: Bethanidine, like bretylium, is not in a free diffusion equilibrium with tissue but is selectively concentrated and bound in heart, sympathetic nerves, liver, and spleen.[55] The therapeutic effect of bretylium correlates with its myocardial and not its plasma concentration.[56] Bethanidine very likely has similar kinetic characteristics. Corder[57] has calculated the steady state volume distribution equilibrium for bethanidine at 2.7 liters/mg, which indicates that a large proportion of the drug is outside the bloodstream.

While similar in chemical structure and pharmacologic characteristics, bretylium is poorly absorbed from the gut because the strong fixed positive charge in the side chain limits lipid solubility.[39] In contrast, bethanidine is likely to be rapidly transported across the gut and into myocardial cells because the dimethylguanidine on the side chain is more lipid-soluble then the charged quanternary ammonium (Fig. 3). In dogs, the VF threshold rises 10 minutes after oral bethanidine.[8] The prompt suppression of VT also indicates a rapid onset of action in man (Fig. 1).

Adequate potassium required for efficacy: Bethanidine, like bretylium, probably acts directly on the myocardial cell, altering potassium, sodium, and calcium transport and distribution.[6,8] Specific studies on the mechanism of action of bethanidine, however, have not been done. An important element in bretylium efficacy, which also appears true for bethanidine, is that myocardial and serum potassium must be normal for the drug to be effective.[6,25] Neither drug appears to work well when potassium is depleted. Since many cardiac patients with arrhythmias are receiving diuretic agents, digitalis glycosides, and conventional antiarrhythmic drugs, all of which tend to deplete intracellular potassium, it is important to assess and restore myocardial potassium to normal levels in patients receiving bethanidine. Bethanidine tends to reduce serum potassium as potassium shifts into cells. Because serum potassium may be in the normal range even when

myocardial potassium is low, it is our practice to keep serum potassium in the high normal range (4.5 mEq/liter).

Acknowledgment

We appreciate the help of Robert Keenan, MD, of A. H. Robins Company, who supplied bethanidine for this study.

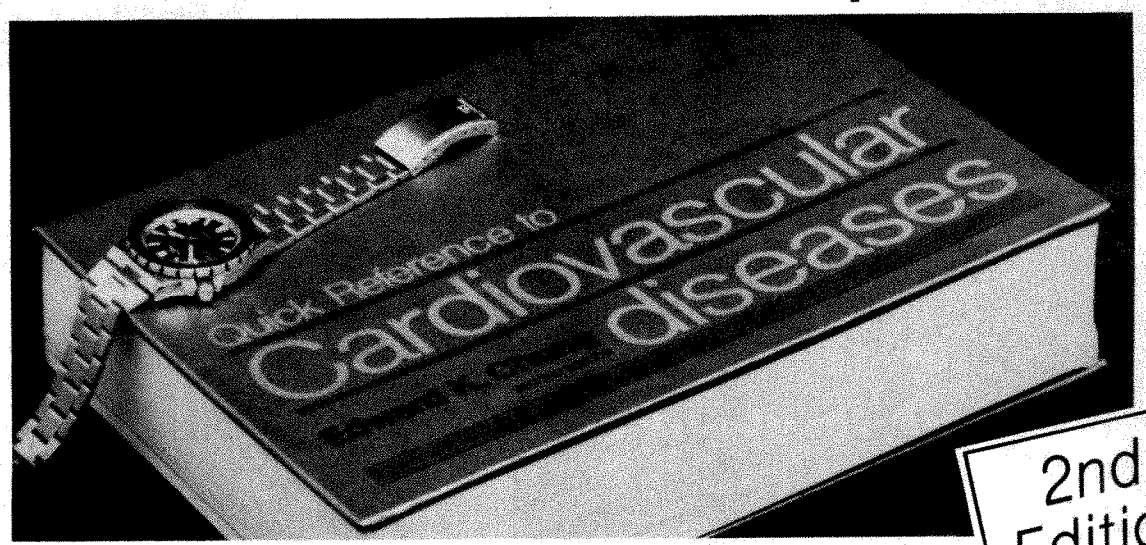
Ready when there's no time to spare



2nd Edition

Quick Reference to **Cardiovascular Diseases**

Edited by EDWARD K. CHUNG, M.D., F.A.C.P., F.A.C.C.
45 Contributors

When you need facts *fast*—Dr. Chung and his colleagues are "on call" with practical, clinical information. In easy-to-find fashion, this concise reference describes common cardiovascular diseases that are frequently encountered in daily practice, providing up-to-date specifics to assist in patient care.

Each chapter is designed for maximum convenience, with clinically relevant information organized within an outline structure for quick reference to both diagnosis and management. Each entry is numbered to reveal critical data at a glance. Most chapters include general considerations, definitions, etiology, pathophysiology, classifications, symptoms and signs, laboratory findings, diagnosis, differential diagnosis, complications, management, and prognosis.

New chapters in the second edition include *Risk Factors for Coronary Artery Disease, Exercise Prescription for Patients with Coronary Artery Disease and for Healthy Individuals, Sick Sinus Syndrome, Coronary Bypass Surgery,* and *Electrolyte Imbalance and Heart Function.* All commonly used cardiac tests are also included.

Busy primary care physicians, house staff, cardiac care nurses, and medical students will find this new second edition a valuable source of practical information. QUICK REFERENCE TO CARDIOVASCULAR DISEASES also offers much of interest to anesthesiologists and cardiac and chest surgeons.

Acclaim for the 1st Edition

". . . a must as a source of immediate and pertinent information in every emergency department."
Annals of Emergency Medicine

". . . will be a welcome addition to the bookshelves of all busy medical wards, the only trouble being that one doubts whether the book would stay there very long—such is its value!" *British Journal of Hospital Medicine*

". . . the reader is quickly reminded of the important considerations in each disease . . . recommended highly."
Annals of Thoracic Surgery

". . . eminently useful to the clinician." *Military Medicine*

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books AJCJ2
Box C-757, Brooklyn, New York 11205

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($38.00 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

- ☐ Full payment enclosed, publisher pays shipping.
- ☐ Please bill me, plus cost of shipping.
- ☐ Charge my credit card: ☐ MasterCard ☐ Visa.

CARDIOLOGISTS

Private Practice Opportunities Tailor-Made For You.

Deciding upon the community where your skills are in the greatest demand can be an arduous task. Your choice is important to your career, and Humana, with more than 89 hospitals nationwide, can help you to select the location that best suits your professional and personal needs.

Furthermore, Humana can assist you in establishing a private practice. Whether you desire a solo, group or associate arrangement, Humana can make it happen. And, in many cases, financial assistance is available.

Humana offers you a wealth of choices from which to choose and currently we have outstanding Cardiology opportunities in the following states:

- Alabama
- Florida
- Virginia
- Texas
- West Virginia

So get moving. For further information, send your curriculum vitae to the address below, or call Gordon Crawford, Manager, Professional Relations TOLL-FREE: 800-626-1590. There is no obligation.

Humana
The Hospital Company
Dept. M-10
1800 First National Tower
Louisville, Kentucky 40201

Humana: We make it our practice to help yours.

once-a-day

Transderm-Nitro®

nitroglycerin

Exclusive rate-controlling membrane delivers hour-by-hour precision dosage

- Specially designed copolymer membrane governs, and limits, rate at which drug diffuses from the system to the skin.
- Similar to an intravenous *infusion*, Transderm-Nitro delivers medication at a constant rate.
- Patients are protected against extremely high concentrations being reached even where skin is unusually permeable.

(actual size)

(approx. thinness)

Magnified cross section of Transderm-Nitro system

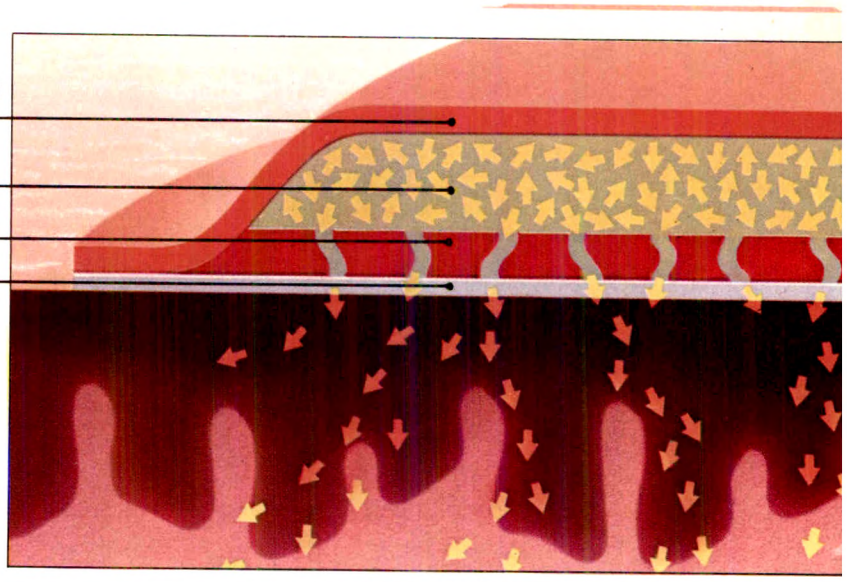
impermeable water-resistant backing layer

nitroglycerin reservoir

rate-controlling membrane

hypoallergenic contact adhesive

Contains an initial dose of medication to saturate skin-binding sites so that absorption begins immediately



Precision dosage system assures 24-hour angina protection

Steady, sustained 24-hour nitroglycerin levels

Constant protection against angina attacks assured by uninterrupted plasma concentrations of nitroglycerin: Transderm-Nitro 5 rated to release 5 mg/24 hours; Transderm-Nitro 10 rated to release 10 mg/24 hours.

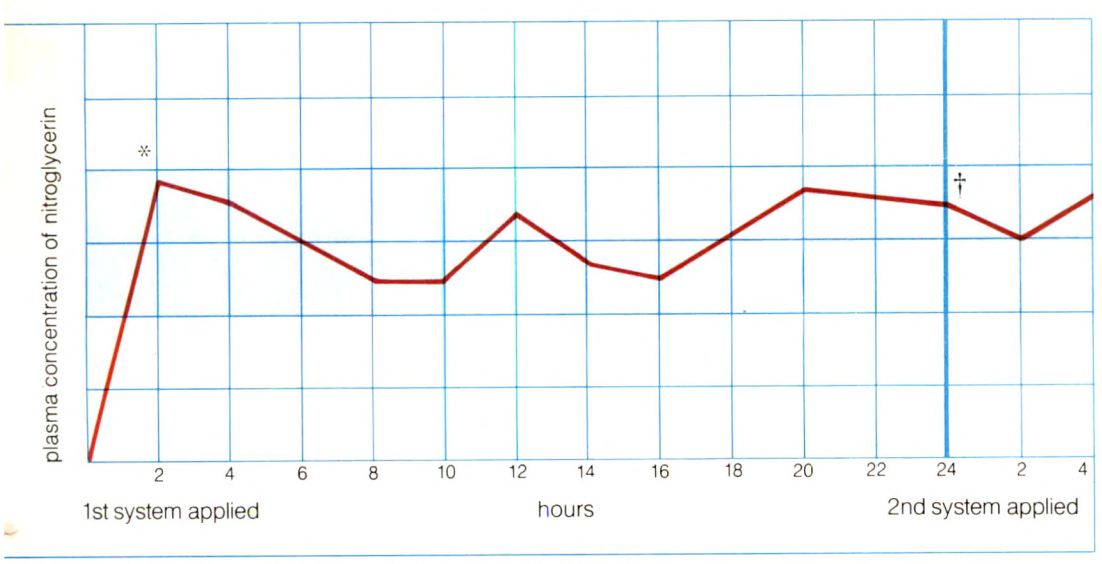
Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

System is simple and easy to use

- Every 24 hours the old system is removed and the new one applied.
- Therapeutic effect can be anticipated 30 minutes after application and maintained for 30 minutes following removal.
- Can be applied anywhere on the body except the distal extremities.

An advance beyond tablets and ointments

- 24-hour sustained therapeutic blood levels of nitroglycerin
- Precise dosage control
- Ease of administration...avoids mess and inconvenience of ointments
- Once-a-day dosage to enhance compliance
- May be worn while swimming, bathing and showering



First measurement in this study was taken 2 hours. However, a therapeutic effect can be anticipated 30 minutes after application of the system, and will be maintained for 30 minutes after its removal.

†After 24 hours, system is removed and a new one is applied to another site. Renewal of the system does not result in any significant alteration in the plasma levels, as long as the change is made without delay.

CIBA

For full details, please see the prescribing information on the next page.

Transderm®-Nitro nitroglycerin

Once-a-day, 24-hour protection against angina attacks

System can be applied anywhere except distal extremities. Doesn't compromise daily activities.

Transderm®-Nitro
(nitroglycerin)
Transdermal Therapeutic System

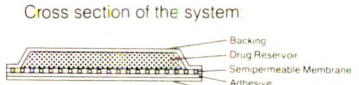
DESCRIPTION

Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system. 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface toward the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS

When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION

Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension, especially during orthostasis, indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS

A patient leaflet is supplied with the systems.

Continuous Monitoring of Left Ventricular Performance With The Computerized Nuclear Probe During Laryngoscopy and Intubation Before Coronary Artery Bypass Surgery

ROBERT W. GILES, MD, BS, HARVEY J. BERGER, MD, PAUL G. BARASH, MD, SANJIWAN TARABADKAR, MD, PETER G. MARX, BM, BCh, GRAEME L. HAMMOND, MD, ALEXANDER S. GEHA, MD, HILLEL LAKS, MD, and BARRY L. ZARET, MD

Left ventricular performance was monitored serially in 25 patients during laryngoscopy and intubation in the anesthetic induction period before elective coronary artery bypass surgery using the labeled equilibrium blood pool and the computerized nuclear probe. Left ventricular ejection fraction was obtained preoperatively, after induction of anesthesia but before endotracheal intubation, immediately after intubation, and at 1 minute intervals thereafter for 10 minutes. In all patients, there was an immediate decrease (mean 16%) in left ventricular ejection fraction accompanying the reflex hypertension and tachycardia occurring during laryngoscopy and endotracheal intubation; it was significantly depressed for 3 minutes with the concomitant hemodynamic changes. Seven patients did not demonstrate a recovery of left ventricular ejection fraction to the preintubation value. In 10 healthy noncardiac patients undergoing orthopedic surgery, after an identical anesthetic induction sequence and intubation, there was a similar decrease in ejection fraction, but of shorter duration. In these patients the recovery of left ventricular performance preceded the recovery of blood pressure and heart rate.

This study demonstrates that profound decreases in left ventricular performance accompany the reflex hypertension and tachycardia occurring during endotracheal intubation and that there is persisting depression of left ventricular function in some patients with coronary artery disease. These findings indicate the potential utility of the computerized nuclear probe for monitoring ventricular performance during this critical period.

Reflex vasoconstriction may result in substantial pathophysiologic consequences in patients with coronary artery disease. During induction of anesthesia, laryngoscopy and intubation can be associated with reflex hypertension and tachycardia due to autonomic stimulation.[1,2] In patients with coronary artery disease, these hemodynamic alterations may lead to an imbalance in myocardial oxygen supply-demand relationships at the time of anesthesia.[3] This may result in myocardial ischemia, impairment in cardiac performance, and if sustained, myocardial necrosis. In addition, acute alterations in afterload may affect ventricular function directly.

In the present study, we monitored left ventricular performance during laryngoscopy and endotracheal intubation in patients undergoing elective coronary artery bypass surgery. Global left ventricular performance was monitored using the computerized nuclear probe, a radiation detector system that provides accurate continuous sampling of data necessary for assessment of rapidly changing reflex events.[4-6] Radionuclide variables were obtained simultaneously with hemodynamic and electrocardiographic data.

From the Cardiology Section, Department of Internal Medicine; Nuclear Medicine Section, Department of Diagnostic Radiology; Department of Anesthesiology; and the Cardiothoracic Surgical Section, Department of Surgery, Yale University School of Medicine, New Haven, Connecticut. Methods

Patient population: We studied 25 patients (24 men, 1 woman) with symptomatic coronary artery disease undergoing elective coronary artery bypass surgery. Their mean age was 57 years (range 38 to 68). Thirteen patients had had a previous myocardial infarction 1 month to 19 years before the present study. All patients had stable angina pectoris. Six were in New York Heart Association functional class I or II, and 19 were in class III or IV. Patients with unstable or preinfarction angina or associated valvular heart disease and those undergoing left ventricular aneurysm resection were excluded. Decisions on patient participation were based on the patient's and referring physician's consent as well as laboratory logistics. The population studied was a representative but nonconsecutive sample of those undergoing elective coronary revascularization surgery at Yale-New Haven Hospital. Twenty-three patients were receiving propranolol at a mean dose of 240 mg/day (range 60 to 680). Propranolol was continued until 4 hours before surgery. Nineteen patients were receiving long-acting nitrates, 4 were receiving digoxin, and 6 were receiving diuretics.

Preoperatively, the mean left ventricular ejection fraction in the group was 57% (range 26 to 82) determined by gated equilibrium cardiac blood pool imaging (see later). Fifteen of the 25 patients had a normal ejection fraction (greater than 55%). Twenty patients had triple vessel disease (including 1 patient with left main coronary artery stenosis), 4 patients had double vessel disease, and 1 patient had a single lesion involving the left anterior descending artery. This study was approved by the Yale University School of Medicine Human Investigation Committee, and informed consent was obtained from all patients.

Preoperative and operative protocol: On the day before surgery, left ventricular performance was measured both with the computerized nuclear probe (Bios) and conventional scintillation camera gated blood pool imaging. Camera studies were performed with a single crystal scintillation camera (Siemens LEM) interfaced to a nuclear medicine computer system (Medical Data Systems Mugacart). Left ventricular ejection fraction determined by the nuclear probe and multigated blood pool imaging correlated closely ($r = 0.92$). This finding is comparable to previously reported correlations from this and other laboratories.[5-9]

On the day of surgery, after premedication and placing of intravascular monitoring catheters, the patient's blood pool was labelled and the nuclear probe was positioned. Hemodynamic and radionuclide data were obtained before induction immediately before laryngoscopy (baseline), during laryngoscopy and intubation, and at 1 minute intervals thereafter for 10 minutes. The preintubation values serve as baseline data for the study since they represent the final hemodynamic steady state before the intervention of laryngoscopy and endotracheal intubation. Particular care was taken to ensure the stability of the probe's position on the chest during laryngoscopy and intubation.

Nuclear probe technique: The patient's red blood cells were labelled in vivo with 20 to 25 mCi of technetium-99m pertechnetate. The probe was positioned at the left ventricular and background regions of interest, using positioning algorithms and operator routines developed and validated in this laboratory.[6] Left ventricular ejection fraction is calculated from background-corrected end-diastolic and end-systolic counts. These calculations assume a stable equilibrium blood pool and constant background level. The background activity level is recorded at the beginning of the induction of anesthesia and is automatically decay corrected during the study period (approximately 20 minutes). The variability of manually derived beat-to-beat ejection fraction is ±5.8% (in absolute ejection fraction units). This represents twice the pooled standard deviation of ejection fraction measurements in 710 individual beats analyzed in 71 patients.[6] Based upon these variability data, a value of 6% or greater was used in the present study to signify a nonrandom change.

Changes in end-diastolic counts and the difference between end-diastolic and end-systolic counts also indicate proportional changes in end-diastolic volume and stroke volume, respectively. The microprocessor of the nuclear probe calculates and displays the mean beat-to-beat ejection fraction, relative change in end-diastolic counts and stroke counts, and relative change in derived cardiac output on a 10 second sweep. These data were used for analysis. The analog data from the nuclear probe also were interfaced to a multichannel strip chart recorder allowing simultaneous recording of the electrocardiogram, pressure measurements, and radionuclide time-activity curves (Fig. 1).

Anesthetic technique: A standard anesthesia sequence for patients undergoing electric coronary artery bypass surgery at this institution was used. All patients received a similar pharmacologic induction sequence and were monitored in a comparable manner. Premedication with morphine sulphate (0.15 mg/kg) and scopolamine (0.4 mg) was administered intramuscularly 90 minutes before arrival in the operating room. All patients were adequately sedated on arrival at the operating room and no patient exhibited evidence of myocardial ischemia. At the time of arrival in the operating room, a thermodilution quadruple lumen catheter was positioned in the pulmonary artery percutaneously by way of the internal jugular vein. A radial artery catheter also was placed for recording systemic blood pressure. All measurements were obtained at end-exhalation. A standard electrocardiographic V_5 lead was monitored continuously throughout the study period. Arterial oxygen and carbon dioxide tensions and pH were assessed before intubation, at intubation, and 10 minutes after intubation.

Anesthesia was induced with intravenous diazepam (0.3 mg/kg) and nitrous oxide/oxygen (3:2). Enflurane inhalation was titrated as clinically indicated for adequate depth of anesthesia. During induction and before laryngoscopy and intubation, the patients were hemodynamically stable with maintenance of cardiac output. Muscle relaxation for laryngoscopy and endotracheal intubation was achieved with a continuous infusion of succinylcholine (0.2% solution). Laryngoscopy and endotracheal intubation were performed with a #3 MacIntosh blade laryngoscope and an 8.0 mm tube lubricated with a nonanesthetic water-soluble gel. The duration of laryngoscopy and intubation averaged 11 seconds (range 4 to 22). All patients received enflurane after intubation, and 10 patients received enflurane before laryngoscopy and intubation. In terms of clinical, angiographic, and functional assessment as well as hemodynamic responses during the study, these 10 patients were indistinguishable from those who did not receive enflurane before intubation. Thus, the data from all 25 patients are analyzed together.

Technique controls: To assess possible changes in background activity (a factor that could influence ejection fraction measurements) induced by laryngoscopy and intubation, 2 patients undergoing coronary artery bypass surgery were studied with the probe positioned over the background region of interest for the entire induction period. The same study protocol was used; however, only background activity was counted. An assumption is made that background activity remains relatively stable throughout the study period. Unrecognized changes in background activity during anesthesia

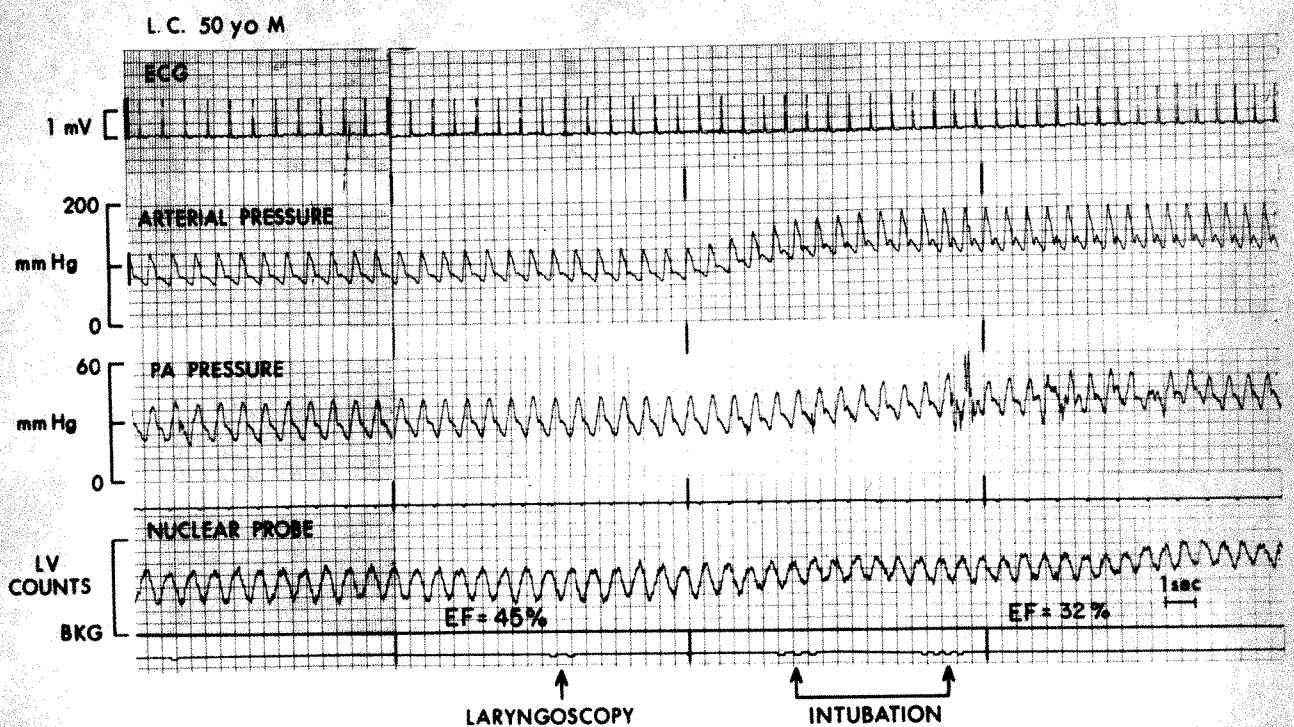

FIGURE 1. Simultaneous recording of the electrocardiogram (ECG), arterial pressure, pulmonary artery (PA) pressure, and radionuclide left ventricular (LV) time-activity curve (NUCLEAR PROBE). **Arrows** indicate the beginning of laryngoscopy and the actual time for intubation. Arterial pressure increases within 5 seconds of the beginning of laryngoscopy accompanied by increases in heart rate and PA pressure. Left ventricular ejection fraction (EF) is 45% before intubation, and decreases to 32% within 15 seconds after laryngoscopy and intubation. BKG = background activity level.

induction would affect the reliability of serial determinations of ejection fraction because the background level is recorded at the beginning of the study and used for all subsequent calculations. In these 2 patients the relative change in background counts was less than ±2% of the preintubation value. The change in background counts was calculated to result in a maximum of ±4% absolute change in ejection fraction (ejection fraction [EF] units) due to potential changes in background activity during the study period.

To assess possible changes in ejection fraction due to assisted ventilation, this was performed in 3 cooperative conscious patients on the day before surgery using a face mask in a manner comparable to that employed during induction of anesthesia. Probe monitoring of ejection fraction was obtained during this period. In these patients, airway pressures similar to those recorded during induction were achieved to simulate the changes in intrathoracic pressure during assisted ventilation after muscle relaxants are administered. There was less than a ±3% absolute change in the recorded ejection fraction in these patients.

Healthy noncardiac patients (control group): Ten healthy patients aged 20 to 32 years (mean 25) without clinical or electrocardiographic evidence of cardiac disease, undergoing elective orthopedic surgical procedures also were studied. Premedication, anesthesia induction, laryngoscopy, and intubation were performed exactly as in the patients with coronary artery disease. In this group, invasive intravascular monitoring was not performed. Blood pressures were measured externally by a Dynamap (model 845) which noninvasively determines blood pressure at 30 second intervals. The nuclear probe protocol was identical to that in the study group.

Statistical analysis: Analysis of variance for repeated measures was performed using the general linear model of the Statistical Analysis System.[10] Contrasts were obtained between preintubation baseline data and subsequent serial determinations. Group data are presented as the least squares mean ± least squares standard error. The changes in hemodynamic and functional variables at intubation in various patient groups were compared by Student's *t* test. Changes in ejection fraction are expressed in ejection fraction units. The time to recovery of ejection fraction is expressed as the median value and compared in the 2 study groups by the Wilcoxon rank sum test.[11] Probability (p) less than 0.05 was considered significant.

Results

Patients with coronary artery disease (Table I): Hemodynamic and ventricular performance variables were stable until the period of laryngoscopy and intubation. However, all patients with coronary disease had an immediate decrease in left ventricular ejection fraction associated with laryngoscopy and intubation (Fig. 2). Absolute decrease in ejection fraction ranged from 4 to 26% (EF units). Ejection fraction decreased from 50 ± 3% at preintubation to 34 ± 3% at intubation ($p < 0.0001$), and remained significantly decreased for 3 minutes after intubation (45 ± 3%, $p < 0.002$). Systolic blood pressure increased from 116 ± 4 before intubation to 152 ± 3 mm Hg at intubation ($p < 0.0001$) and remained significantly elevated for 3 minutes after intubation ($p < 0.045$). Heart rate increased from 57 ± 3 to

TABLE I Effects of Intubation on Left Ventricular Function in Patients With Coronary Artery Disease (n = 25)

Period	LVEF (%)	p	Systolic BP (mm Hg)	p	HR (bpm)	p	PCWP (mm Hg)	p	EDC (%)	p
Preintubation	50 ± 3	...	116 ± 3	...	57 ± 3	...	16 ± 2	...	100%	...
Intubation	34 ± 3	<0.0001	152 ± 3	<0.0001	72 ± 3	<0.0001	23 ± 2	<0.0001	97 ± 2	NS
1 minute	38 ± 3	<0.0001	153 ± 5	<0.0001	78 ± 3	<0.0001	19 ± 2	<0.009	98 ± 2	NS
2 minutes	44 ± 3	<0.0001	131 ± 5	<0.0001	71 ± 3	<0.0001	22 ± 2	<0.008	99 ± 2	NS
3 minutes	45 ± 5	<0.002	122 ± 4	<0.045	66 ± 3	<0.0001	19 ± 2	NS	102 ± 2	NS
4 minutes	50 ± 3	NS	117 ± 5	NS	61 ± 3	NS	19 ± 2	NS	103 ± 2	NS
5 minutes	47 ± 3	NS	114 ± 4	NS	59 ± 3	NS	16 ± 2	NS	102 ± 2	NS
10 minutes	47 ± 3	NS	109 ± 4	NS	55 ± 3	NS	19 ± 2	NS	102 ± 2	NS

Results are expressed at least squares mean ± least squares standard error. Data are compared with preintubation values. Overall each variable except EDC had highly significant effects ($p < 0.0001$). BP = blood pressure; EDC = end-diastolic counts as a percentage of the preintubation value; HR = heart rate in beats/min (bpm); LVEF = left ventricular ejection fraction; NS = not significant (<0.05); PCWP = pulmonary capillary wedge pressure.

71 ± 3 beats/min at intubation ($p < 0.0001$). Heart rate was elevated significantly for 3 minutes after intubation. Although pulmonary capillary wedge pressure increased from 16 ± 3 to 23 ± 2 mm Hg at intubation ($p < 0.0001$), the duration was less prolonged than for either heart rate or blood pressure changes; significant elevation was noted for 2 minutes after intubation (Fig. 2). End-diastolic counts did not change throughout the study (p = NS). At intubation, stroke counts decreased by 31 ± 4% ($p < 0.0001$); the time course paralleled that for ejection fraction. Neither cardiac index, determined by the thermodilution technique, nor relative cardiac output, determined by the probe, changed significantly. Cardiac index was comparable at preintubation and intubation (2.7 ± 0.14 versus 2.9 ± 0.15 liters/min per m^2, p = NS). As would be anticipated from the changes in blood pressure and cardiac index, peripheral vascular resistance increased by 22% during intubation.

The median time to recovery of left ventricular ejection fraction after intubation was 4 minutes (range 2 to 10). In 7 of the 25 patients, ejection fraction did not return to less than 6% (intrinsic variability) of preintubation values by 10 minutes after intubation (Fig. 3). In comparison with the baseline value, the final ejection fraction was 6 to 21% lower. These 7 patients were not distinguishable preoperatively or by baseline clinical or hemodynamic measurements from the 18 patients with full recovery of ejection fraction. In these 7 patients, comparing preintubation to intubation, the systolic blood pressure increased by 42 ± 12 mm Hg, while the heart rate increased by 13 ± 5 beats/min. These changes were not significantly different from the response seen in the 18 patients who had a full recovery

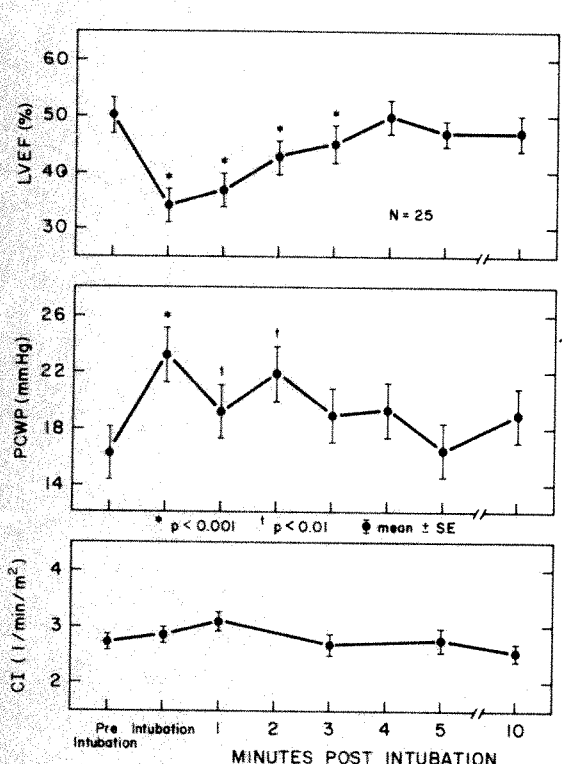

FIGURE 2. Group data for left ventricular ejection fraction (LVEF), pulmonary capillary wedge pressure (PCWP), and thermodilution cardiac index (CI) in patients with coronary artery disease. Results are expressed as least squares mean ± least squares standard error. Data are compared with preintubation values using analysis of variance for repeated measures. Note that LVEF remained depressed for 3 minutes after intubation while PCWP was elevated through 2 minutes. (The cardiac index was not obtained in all patients at 2 and 4 minutes and therefore is not shown.)

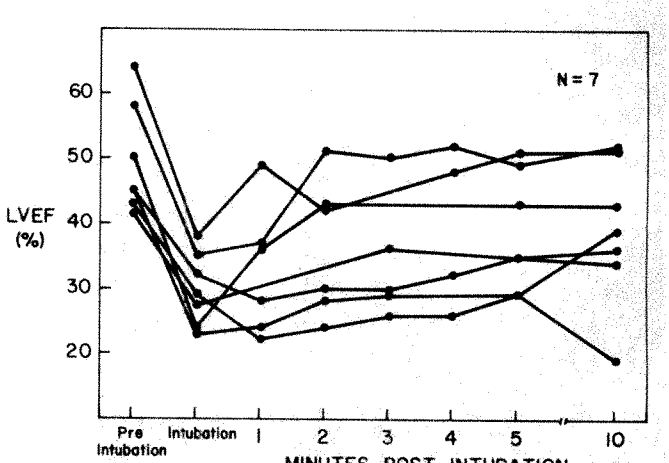

FIGURE 3. Individual left ventricular ejection fraction (LVEF) measurements at specific times during the study period in 7 patients who showed persisting depression of ejection fraction 10 minutes after laryngoscopy and intubation. In none of these patients did the value return to preintubation levels.

TABLE II Effects of Intubation on Left Ventricular Function in Healthy Noncardiac Patients (Control Subjects)

Period	LVEF (%)	p	Systolic BP (mm Hg)	p	HR (bpm)	p	EDC (%)	p
Preintubation	67 ± 3	. . .	107 ± 3	. . .	68 ± 5	. . .	100	. . .
Intubation	48 ± 3	<0.0001	116 ± 3	<0.013	77 ± 5	<0.011	101 ± 2	NS
1 minute	61 ± 3	<0.009	123 ± 3	<0.0001	88 ± 5	<0.0001	100 ± 2	NS
2 minutes	67 ± 2	NS	123 ± 3	<0.0001	87 ± 5	<0.0001	98 ± 2	NS
3 minutes	66 ± 2	NS	116 ± 3	<0.006	80 ± 5	<0.0007	100 ± 2	NS
4 minutes	66 ± 3	NS	108 ± 3	<0.025	71 ± 5	<0.001	98 ± 2	NS
5 minutes	68 ± 3	NS	111 ± 3	NS	75 ± 5	NS	97 ± 2	NS
10 minutes	69 ± 3	NS	106 ± 4	NS	66 ± 6	NS	98 ± 3	NS

Results are expressed as least squares mean ± least squares standard error. Data are compared with preintubation values. Overall each variable except EDC had highly significant effects ($p < 0.0001$). Abbreviations as in Table I.

of ejection fraction after intubation (35 ± 5 mm Hg and 16 ± 3 beats/min, respectively). Although the left ventricular ejection fraction remained depressed after intubation, systolic blood pressure was elevated only through 1 minute after induction ($p < 0.0005$), and heart rate only through 3 minutes ($p < 0.035$). Pulmonary capillary wedge pressure remained significantly elevated for 3 minutes after intubation (18 ± 2 mm Hg before intubation versus 25 ± 3 mm Hg 3 minutes after intubation, $p < 0.02$) in these 7 patients, whereas it was elevated only for the immediate postintubation period in the 18 patients who had a recovery of ejection fraction (18 ± 2 mm Hg before intubation versus 20 ± 2 mm Hg at intubation, $p < 0.002$). Only 2 patients showed ischemic electrocardiographic changes (1.0 mm or greater flat or downsloping S-T segment depression compared with the baseline value); neither was receiving digoxin. Both patients were among the 7 patients who showed persistent depression of ejection fraction 10 minutes after intubation.

Healthy noncardiac patients (Table II): The 10 healthy noncardiac patients, who were receiving no cardiac medication, showed transient decreases in ejection fraction ranging from 3 to 34% (mean 19 ± 3) with intubation. The ejection fraction was 67 ± 3% before intubation and decreased to 48 ± 3% at intubation ($p < 0.0001$). The ejection fraction remained significantly different from preintubation values 1 minute after intubation ($p < 0.009$). The median time to recovery after intubation was 2 minutes (range 1 to 4). This was significantly less than in the patients with coronary artery disease ($p < 0.01$). Moreover, the recovery of ejection fraction preceded the recovery of heart rate and blood pressure, which remained significantly elevated for 4 minutes after intubation ($p < 0.025$). Stroke counts decreased 28 ± 3% at intubation compared with the preintubation value ($p < 0.0002$) and paralleled the changes in ejection fraction. No significant changes in end-diastolic counts or relative cardiac output were noted during the study period.

Discussion

Ventricular function during operative laryngoscopy and intubation: This study demonstrates that the reflex hypertension and tachycardia associated with laryngoscopy and intubation result in profound decreases in left ventricular ejection fraction in patients with coronary artery disease undergoing revascularization surgery. Changes in ventricular performance generally occurred in the absence of ischemic electrocardiographic abnormalities, highlighting the potential value of this radionuclide probe technique for monitoring cardiac patients during this period. In 7 of 25 patients, depressed left ventricular ejection fraction compared with preintubation values persisted for the 10 minute monitoring period after intubation. The delayed recovery of ventricular function may indicate ongoing myocardial ischemia or damage, or both or altered ventricular reserve following afterload stress in the absence of ischemia. However, this period represents only 1 portion of the operative procedure during which myocardial damage could occur.[12] Further stress, such as hypertension during sternotomy[3] or inadequate myocardial protection[12,13] also could account for ischemia and infarction. The early operative period of anesthesia induction, laryngoscopy, and intubation should be viewed as a time for the potential initiation of a series of pathophysiologic events that may lead to hemodynamic compromise.

Although the patients with coronary disease studied in this report were clinically stable and were undergoing elective coronary revascularization, all were symptomatic and had extensive disease. Therefore, extrapolating these results to all patients with coronary artery disease undergoing both cardiac and noncardiac surgery should be done cautiously. Nevertheless, despite continued improvement in cardiac surgical techniques and improved methods of myocardial preservation, a distinct incidence of perioperative infarction after coronary surgery still persists.[12,14,15] Several studies also have demonstrated a substantial risk of postoperative infarction in cardiac patients undergoing noncardiac surgery.[16,17]

Mechanisms: Several potential mechanisms may explain our observations. The depression of left ventricular performance is probably a manifestation of altered functional reserve in the face of an acute increase in afterload[18] ("afterload mismatch"). The average increase in blood pressure in these patients was 36 mm Hg. Although left ventricular filling pressure is increased, failure to increase left ventricular end-diastolic volume suggests that the left ventricle in coronary dis-

ease may not be capable of evoking adequate preload reserve.[19] Alternatively, a limited ability to augment coronary flow in response to an acute increase in myocardial oxygen demands may result in myocardial ischemia and functional depression.

Another possible mechanism involves alterations in coronary vascular resistance or coronary artery spasm associated with laryngoscopy and intubation. The magnitude of decrease in ejection fraction, which is substantially greater than noted routinely during exercise-induced ischemia in coronary artery disease,[20] suggests that supply as well as demand may be altered. Mechanistically, this could parallel cold pressor stimulation,[21] an event resulting in altered coronary resistance and peripheral vascular resistance changes comparable to those observed during laryngoscopy and intubation. Alterations in coronary vascular resistance after cold pressor stimulation appear to be mediated by alpha-adrenergic mechanisms.[21] Most patients in our study were receiving substantial doses of propranolol at the time of surgery. Such beta-adrenergic blockade may result in unopposed accentuated alpha-adrenergic effects in both the peripheral and coronary circulations.[22] Propranolol also may limit the ventricular response to acute afterload stress in these patients.

Comparison with observations in normal persons: Major decreases in left ventricular ejection fraction also were observed in healthy noncardiac patients undergoing a comparable anesthetic protocol. We recognize that these patients were not age-matched to the coronary study group, nor were they intended to represent a control population. It virtually would be impossible to obtain an appropriate age-matched group undergoing elective surgery in whom angiography had recently ruled out significant coronary artery disease. The ejection fraction in this group fell by a degree comparable to that seen in the coronary patients; however, the decrease in ejection fraction was sustained for a shorter period of time after intubation than in the coronary patients. This temporal difference between groups could be dependent upon coronary disease, as well as patient age or propranolol therapy. Even the normal ventricle will manifest depression in performance when faced with a marked acute increase in afterload.[18,23] However, sympathetic stimulation may result in enhanced myocardial performance.[19] In these healthy noncardiac patients, the recovery of left ventricular performance preceded the recovery of altered afterload.

Methodology: The computerized nuclear probe appears to be an appropriate instrument for monitoring ventricular performance in the operating room. The ability to obtain serial data concerning global ventricular function on a beat-to-beat basis[5,6,24,25,26] provides a means of studying rapidly changing pathophysiologic reflex events such as those observed in this investigation. Such analysis would not be possible using conventional scintillation camera techniques. Studies involving technique controls indicate clearly that the results obtained are not a function of artifacts induced by either probe positioning or changes in background activity.

Implications of study: In patients with clinically significant heart disease, hypertension and tachycardia have been noted frequently with a wide variety of anesthetic induction techniques.[27–29] Although deeper levels of anesthesia associated with high concentrations of potent inhalation agents may blunt this response, the circulatory depression observed in patients with compromised cardiovascular function render this an unsatisfactory approach.[30] However, it is relevant to note that the hypertensive and tachycardic responses have been blunted, but not consistently eliminated, by topical oral pharyngeal anesthesia,[31] and the hypertensive effects have been eliminated through the use of vasodilators such as nitroprusside.[32] Preliminary studies have shown that the left ventricular responses to laryngoscopy and intubation may be blocked by the use of the high potency synthetic narcotic, fentanyl, as an anesthetic agent.[33] Thus, a variety of therapeutic options may be available for limiting or altering this ventricular response. However, further long-term studies are needed to assess the overall value of radionuclide monitoring in this period and its relation to subsequent patient outcome.

Constrictive Pericarditis as a Complication of Cardiac Surgery: Recognition of an Entity

MICHAEL A. KUTCHER, MD, SPENCER B. KING III, MD, BENJAMIN N. ALIMURUNG, MD, JOSEPH M. CRAVER, MD, and R. BRUCE LOGUE, MD

Among 5,207 adult patients who underwent cardiac surgery, postoperative constrictive pericarditis was recognized in 11 patients (0.2% incidence rate). Seven patients had coronary arterial bypass grafting and 4 had valve replacement; the pericardium was left open in all cases. The average interval between surgery and presentation of pericardial constriction was 82 days (range 14 to 186). M mode echocardiography revealed epicardial and pericardial thickening in 7 cases and variable degrees of posterior pericardial effusion in 5 cases. Cardiac catheterization demonstrated uniformity of diastolic pressures with a characteristic early diastolic dip and late plateau pattern. Two patients responded to medical therapy for chronic pericarditis. One patient had a limited parietal pericardiectomy followed by recurrent constrictive pericarditis that eventually stabilized with medical therapy. The other 8 patients required radical pericardiectomy.

The pathophysiology of constriction after surgery is unclear. Its clinical expression involves a wide spectrum of presentation and therapeutic response. Constrictive pericarditis may be a complication of cardiac surgery in spite of an open pericardium and should be considered in postoperative patients who present with deteriorating cardiac function.

The cause of pericardial constriction is varied and ranges from idiopathic to the major categories of hereditary factors, infection, connective tissue disorders, metabolic disorders, trauma, radiation, and neoplasm.[1] Although open heart surgery involves a degree of trauma to the pericardium, constrictive pericarditis has been considered a rare complication of cardiac surgery,[2] especially when the pericardium is left open. However, several case reports[3-9] of constrictive pericarditis after such surgery have appeared.

In our institution, a small cluster of patients presenting with pericardial constriction after cardiac surgery was recently recognized.[10] This prompted us to review our overall experience with this condition. In this paper we summarize the clinical presentation of constrictive pericarditis as a complication of cardiac surgery in order to set guidelines for the recognition and management of this entity.

Methods

Study patients: Among 5,207 patients undergoing cardiac surgery at Emory University Hospital from 1969 through 1979, postoperative constrictive pericarditis was recognized in 11 patients. The hospital charts, diagnostic studies, cardiac catheterization data, operative reports, pathologic specimens, and follow-up data on these patients were retrospectively reviewed.

From the Division of Cardiology, Division of Thoracic Surgery, Emory University School of Medicine, Woodruff Medical Center, Atlanta, Georgia. Manuscript received July 27, 1981; revised manuscript received March 9, 1982, accepted March 16, 1982.

Address for reprints: Spencer B. King III, MD, Emory University Clinic, 1365 Clifton Road, Atlanta, Georgia 30322.

The patients (Table I) consisted of 10 men and 1 woman, aged 32 to 64 years (mean 53). All patients had cardiac catheterization for the diagnosis of their primary cardiac disease. Seven patients underwent coronary arterial bypass graft surgery for severe coronary atherosclerotic heart disease. Three patients with rheumatic heart disease required mitral valve replacement. One patient underwent aortic valve replacement for calcific aortic stenosis.

The surgical technique included the following common procedures: (1) median sternotomy, (2) cardiopulmonary bypass with systemic hypothermia at 28°C, (3) cardioplegic arrest, (4) local topical hypothermia with iced saline solution, (5) pericardial irrigation, and (6) pericardium left open on sternal closure.

Diagnostic studies: Long-term evaluation was performed by primary care cardiologists in the community with periodic referral to the Emory University Clinic. Criteria for the diagnosis of constrictive pericarditis after cardiac surgery were: (1) symptoms and signs; (2) diagnostic studies such as electrocardiogram, chest X-ray film, and M mode echocardiogram suggesting constrictive pericarditis; (3) cardiac catheterization hemodynamic data compatible with a constrictive physiology; and (4) confirmation of constrictive pathology at the time of reoperation with improved hemodynamics after pericardial stripping—or resolution of the clinical manifestations of pericardial constriction after medical therapy directed toward chronic pericarditis.

11	32M	MVR	5/79	Isotonic saline	29	S

AVR = aortic valve replacement; CABG = coronary arterial bypass surgery and number of vessels bypassed; M = medical therapy (diuretic drugs, anti-inflammatory agents or steroids, or both); MVR = mitral valve replacement; S = surgical therapy (radical pericardiectomy).
* 80 mg gentamicin sulfate, 1 g cephalothin and 1,000 cc normal saline solution. † Concentrations varying from 1:20 to 1:1 povidone-iodine (Betadine®) and normal saline solution.

diastinum.[11,12] An antibiotic solution was used in 2 patients (Cases 1 and 2), and 4 patients (Cases 3, 9, 10 and 11) had irrigation with isotonic saline solution. In the retrospective review, there was no consistent record to determine the frequency with which each of the 3 irrigation solutions was used in the 5,207 patients undergoing cardiac surgery. The type of pericardial irrigation solution utilized was determined by the individual surgeon's preference.

Postoperative events (Table II): Temporary epicardial atrial and ventricular pacemaker wires were placed in 5 patients before chest closure. All of these wires were removed 3 to 5 days after surgery without apparent excessive bleeding or cardiac tamponade. Mediastinal chest tube drainage was normal except in 1 patient (Case 8) who required postoperative exploration for excessive hemorrhage.

During the postoperative period, only 1 patient (Case 7) had diffuse S-T and T wave electrocardiographic changes compatible with acute pericarditis. Chest X-ray films demonstrated pericardial air in 1 patient and a moderate increase in the cardiac silhouette in 3 patients. Transient postoperative hypertension requiring therapy with intravenous nitroprusside was observed in 6 patients but was not associated with excessive mediastinal bleeding. Some type of early postoperative pericardial event was seen in 7 patients; 2 patients had a pericardial rub that required no therapy, whereas 5 patients had symptoms and signs of pericarditis that necessitated therapy with either steroids or indomethacin or both.

No significant coagulation abnormalities were documented before cardiac surgery, during heparin reversal after cardiopulmonary bypass or in the postoperative period. No patients were given anticoagulant therapy, aspirin, procainamide, hydralazine or diphenylhydantoin. The 4 patients who underwent valve replacement all received a porcine heterograft and did not require long-term anticoagulant therapy.

ASM = abnormal septal motion; ECG = electrocardiogram; Echo = echocardiogram; EPT = epicardial and pericardial thickening; ICS = increased cardiac silhouette; JVD = jugular venous distention; LV = low voltage; Nonspec. ST-T = nonspecific ST-T wave changes; NS = changes not significant; PPE = posterior pericardial effusion; PSM = paradoxical septal motion; PVWNL = prosthetic valve within normal limits; *x* = *x* descent; *y* = *y* descent.

Presentation of Constrictive Pericarditis

Clinical presentation (Table III): Definitive presentation of the symptoms and signs of constrictive pericarditis occurred an average of 82 days after cardiac surgery (range 14 to 186 days) (Table I). All patients had dyspnea and 4 complained of pericarditic chest pain. On physical examination, all patients had some degree of jugular venous distension, and a prominent *x* or *y* descent, or both, was evident in 8 patients. In no case was a significant paradoxical pulse elicited. A pericardial knock was heard in 3 patients and a rub was detected in 3 others. Six patients had pedal edema; 4 had evidence of ascites.

Evaluation of electrocardiographic changes revealed diffuse nonspecific ST-T wave changes in 6 patients and decreased QRS voltage in 3. A moderate increase in the cardiac silhouette on chest X-ray film was seen in 6 patients.

M mode echocardiogram (Table III): Seven patients had evidence of abnormal septal motion. Epicardial and pericardial thickening was seen in 7 patients. In 5 cases, variable degrees of posterior pericardial effusion were present (Fig. 1) but no anterior effusion was detected. Four of these patients with effusion (Cases 4, 5, 6, and 8) eventually underwent pericardiectomy and were found to have a significant posterior pericardial hematoma.

Cardiac catheterization (Table IV): An elevated diastolic plateau between the pressures in the right atrium, right ventricle, pulmonary artery, pulmonary capillary wedge position, and left ventricle (Fig. 2) was present in all but 1 case. Patient 3 had a discrepancy between a right atrial mean pressure of 12 mm Hg and a pulmonary capillary wedge mean pressure of 24 mm Hg, but did demonstrate an equal diastolic plateau between the right ventricle, pulmonary artery, pulmonary wedge, and left ventricle in addition to right atrial and right ventricular waveforms characteristic of constriction. A previous limited parietal pericardiectomy and evidence of generalized left ventricular hypokinesia in this patient may account for the discrepancy.

The right atrial tracing in all cases revealed a characteristic M or W pattern with prominent *x* and *y* descents (Fig. 3). Six patients (Cases 3, 5 to 8 and 11) had moderate prominence of the *y* descent. Of these 6, 3 patients (Cases 5, 6, and 8) had a posterior pericardial effusion on M mode echocardiography with a loculated pericardial hematoma found at the time of repeat surgery. In addition, Patient 4 had equalization of *x* and *y* descents with similar echocardiographic and pathologic findings. The equalization of *x* and *y* waves in this patient and the lack of a significantly dominant *y* wave in the other 6 patients are more consistent with the seroeffusive or elastic pattern of pericarditis described by Hancock[13,14] than with a rigid constriction in which the *y* wave is markedly dominant. Ironically, the 2 patients (Cases 9 and 10) who had a markedly dominant *y* descent suggestive of rigid shell constriction both responded to therapy with diuretic drugs and steroids and did not require pericardiectomy.

The right ventricular tracing in all cases demonstrated an early diastolic dip and a late diastolic plateau (square root sign) that equalized with the left ventricular end-diastolic pressure. In most cases, the right ventricular early diastolic dip did not approach absolute zero and was not always accompanied by a concomitant left ventricular early diastolic dip (Fig. 3) as one would expect in chronic rigid constriction. This divergence from the classic constriction pattern may be attribut-

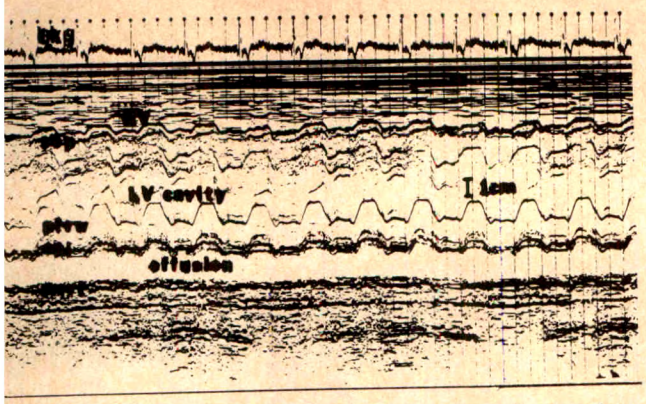

FIGURE 1. Patient 6. Representative M mode echocardiogram, demonstrating boxlike paradoxical interventricular septal (sep) motion and rapid anterior systolic motion of the posterior left ventricular wall (plvw) and epicardium (epi) with flattening in mid and late diastole—all consistent with constrictive pericarditis. In addition, epicardial and pericardial (peri) thickening is present with a significant posterior pericardial effusion. On reoperation, this patient was found to have an organized posterior pericardial hematoma with extensive pericardial fibrosis and constriction. ekg = electrocardiogram; LV = left ventricular; RV = right ventricle.

able to the presence of a more elastic form of constriction.

All the patients had definite constrictive hemodynamics in the resting state. It was not necessary to employ the rapid volume expansion technique of Bush et al.[15] No pericardiocentesis was attempted in view of the lack of evidence for a large anterior effusion.

In a few cases, biplane left ventricular angiography revealed a degree of "square wave" paradoxical septal motion. But overall, there was no consistent sign on either left ventricular or coronary angiography to distinguish pericardial constriction. In the patients with coronary arterial bypass surgery, repeat coronary angiography showed no major progression of disease in native vessels. All saphenous vein grafts were patent except in Patient 5, who had 1 blocked graft. In the patients who had had valve replacement surgery, prosthetic valve function was normal with no significant gradient or regurgitation documented.

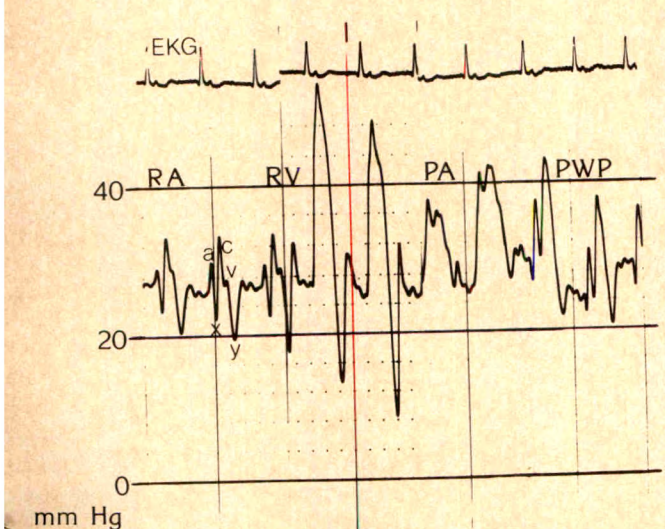

FIGURE 2. Patient 6. Continuous hemodynamic pressure tracings demonstrating a characteristic late diastolic plateau indicative of constriction between the right atrium (RA), right ventricle (RV), pulmonary capillary wedge pressure (PWP), and left ventricular end-diastolic pressure. The right atrial and right ventricular contours are consistent with constriction. Other abbreviations as in Figure 1.

Treatment of Constrictive Pericarditis

After the diagnosis of constrictive pericarditis was made, all patients at some time had a trial of medical therapy of 2 to 8 weeks' duration for chronic pericarditis. Therapy consisted of administration of diuretic drugs (variable doses of furosemide) and steroids (prednisone, 20 to 40 mg/day) or indomethacin (25 mg, 4 times daily). Only 3 patients (Cases 3, 9, and 10) showed improvement and did not require surgery. The remaining 8 patients eventually required radical pericardiectomy.

Medical therapy: The 3 patients who responded to medical therapy form an atypical group that deserves special attention.

Patient 3 was a 55 year old woman who had mitral valve replacement for severe rheumatic mitral regurgitation. She presented approximately 6 months later with constrictive pericarditis and underwent a limited parietal pericardiectomy. Two months after that procedure, cardiac catheterization again demonstrated the hemodynamics of persistent constriction with significant global left ventricular hypokinesia. Institution of a medical regimen of digoxin, diuretic drugs, and steroids for treatment of chronic pericarditis resulted in res-

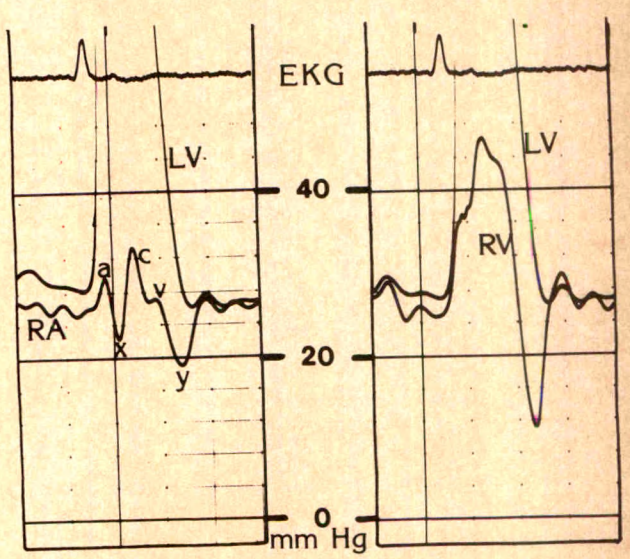

FIGURE 3. Patient 6. Simultaneous right and left heart hemodynamic pressure tracings demonstrating a right atrial (RA) pattern with moderately prominent *y* descent and a right ventricular (RV) early diastolic dip and late plateau. Late diastolic equalization of the pressures in the right atrium, right ventricle, and left ventricle (LV) is present. The right ventricular diastolic dip has not approached zero. The left ventricle does not have an early diastolic dip to correspond to the right atrial *y* wave or the right ventricular early diastolic dip. These patterns may suggest an elastic or seroeffusive form of constriction rather than a rigid constriction. Parenthetically, this patient was found to have a loculated posterior pericardial hematoma and effusion in addition to a fibrotic pericardium at the time of reoperation.

olution of constrictive signs. This case probably represents a constriction of the remaining visceral pericardium with a coexisting congestive cardiomyopathy.

Patient 9 was a 44 year old man who had signs of constrictive pericarditis 14 days after mitral valve replacement. A large posterior pericardial effusion was seen on M mode echocardiography. Repeat cardiac catheterization revealed hemodynamics of constriction. He responded dramatically to medical therapy consisting of administration of diuretic drugs and steroids. In view of the early presentation, this case may represent a late cardiac tamponade or seroeffusive constriction without the development of true fibrosis.

Patient 10 was a 47 year old man whose course after coronary arterial bypass surgery was complicated by recurrent pericarditis and findings of pericardial constriction confirmed by catheterization 2 months later. The clinical signs resolved with a regimen of diuretic drugs and steroids. This case may represent a less advanced form of pericardial fibrosis with a reversible seroeffusive component.

To date, none of the 3 patients have had a recurrence of their pericardial constriction signs or have required pericardiectomy. Steroid and diuretic therapy was successfully discontinued within an average of 2 months.

Surgical therapy: All 8 patients who underwent radical pericardiectomy were found to have extensive parietal and visceral hemorrhagic pericardial fibrosis. An organized hematoma was identified in 4 patients (Cases 4 to 6 and 8) (Fig. 4). Microscopic examination of excised pericardium revealed acute and chronic inflammation with areas of hemorrhage and fibrinous deposition. Bacterial, acid-fast bacillus, and fungal cultures were negative.

Intraoperative hemodynamic monitoring confirmed reversal of constrictive physiology on removal of the parietal and visceral pericardium (Fig. 5). All of the patients demonstrated hemodynamic and clinical improvement after pericardial stripping. The extensive radical pericardiectomy resulted in a nicked saphenous

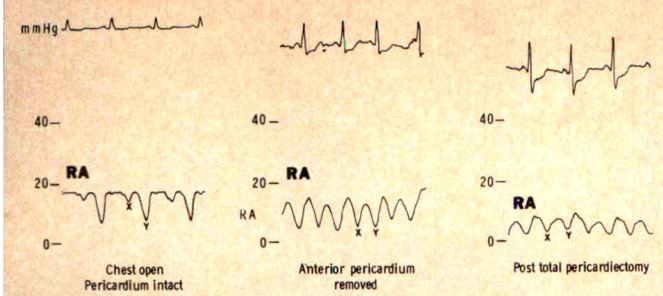

FIGURE 4. Patient 1. Intraoperative hemodynamic monitoring demonstrates (1) elevated right atrial (RA) pressures and dominant *y* descent with pericardium intact; (2) reduced right atrial pressures and equalization of *x* and *y* descents with anterior parietal pericardial stripping; (3) normalization of right atrial pressure tracing after parietal and visceral pericardiectomy.

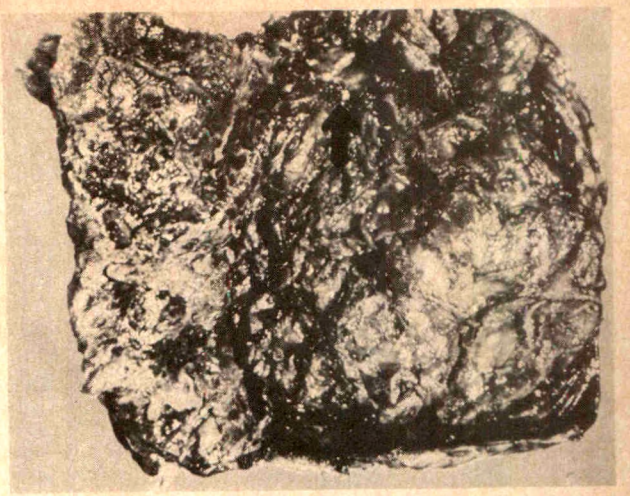

FIGURE 5. Patient 8. Surgical specimen; posterior pericardium. There is evidence of extensive gross hemorrhagic and fibrinous changes. A well organized loculated hematoma is present at the **top part** of the specimen.

vein graft in 2 patients and postoperative exploration for mediastinal bleeding in 2 patients. There was no mortality. To date, all of the surgically treated patients have continued to do well.

Discussion

Pathophysiology: In constrictive pericarditis both the parietal and visceral pericardium are involved in an inflammatory or infiltrative process resulting in fibrosis and eventual impediment to cardiac filling. Trauma to the pericardium in the course of cardiac surgery would seem to offer the appropriate setting for this sequence of events. Hemopericardium secondary to traumatic injury has been reported to lead to pericardial constriction.[16] There has been evidence that air-drying or chemical exposure[17] may destroy the normal fibrinolytic activity of pericardial serosal tissue resulting in a potential nidus for thrombus, adhesions and reactive fibrosis.[18]

Both immediate[19] and late[20] postoperative cardiac tamponade have been reported to be occasional complications of cardiac surgery. The site of postoperative bleeding is extrapericardial in most cases.[21] An open pericardium may actually serve as a collecting reservoir for blood. Our finding of an organized hematoma in the posterior pericardial space in 4 of 8 patients who required pericardiectomy points to the likelihood of old loculated hemorrhage as a pivotal event in the process of inflammation, fibrosis, and constriction.

Additional trauma may be inflicted on the pericardium by the use of pericardial irrigants. Cold injury to the myocardium and pericardium, including fibroplastic proliferation of pericardial serosal surfaces, has been reported[22] when a continuous iced saline slush solution at 0.5°C was used for local hypothermia. In clinical practice, iced saline solutions at temperatures of 2 to 4°C are utilized and rarely decrease the myocardial temperature below 10°C. Recent studies have not detected significant epicardial injury during prolonged topical hypothermia of 5°C to the myocardium.[23] Although local hypothermic solutions under normal conditions do not appear to cause serious pericardial injury, they may involve a degree of disruption to the serosal lining that could become significant when other factors are taken into account.

Recently, Marsa et al.[8] described 3 cases of constrictive pericarditis after cardiac surgery in which it was believed that a povidone-iodine pericardial irrigating solution was a major factor. Our current study demonstrates a definite cluster of 5 cases (Patients 4 to 8) that occurred during the time when a povidone-iodine irrigant solution was used. Ironically, povidone-iodine by itself has very little tissue toxicity and has demonstrated low irritability in open wounds.[24,25] However, combined with factors such as hemorrhage, air-drying and cold injury, it may seriously irritate the serosal lining of the pericardium. In view of this, it may be wise to avoid pericardial irrigating solutions that include povidone-iodine. All 3 patients who responded to medical therapy (Patients 3, 9, and 10) had pericardial irrigation with normal saline solution. It is possible that this may be a significant modifier in the degree of pericardial irritation and subsequent development of irreversible rigid fibrous constriction.

In summary, the pathophysiologic process of constriction in an open pericardium is multifactorial. Irritation of the pericardial layers, both by iced saline solution during cardiopulmonary bypass and by irrigating solutions before chest closure, and postoperative hemorrhage and pooling of blood in the posterior pericardium, appear to be major events. The combination of these factors may initiate inflammation, adhesions, fibrosis and resultant degrees of pericardial constriction with or without effusion.

Clinical aspects: There does not appear to be a clear indicator to predict which patients will have constrictive pericarditis after cardiac surgery. Although 5 of our 11 patients had early postoperative pericarditis that required treatment, this condition does not appear to cause the constrictive disease. Some degree of pericarditis is present in nearly all patients after cardiac surgery, and symptomatic pericarditis requiring therapy occurs in 15 to 30 percent of patients.[2]

The symptoms and signs of postoperative constriction are similar to those of classic chronic constriction

as described by Wood.[26] Postoperative constriction in this study manifested itself an average of 2 to 3 months after cardiac surgery. This time frame is earlier than expected for the development of a true chronic rigid fibrosis but may suggest the evolution of a more elastic type of constrictive process with a possible element of seroeffusion. Cases presenting earlier than 2 months may represent a variation of late tamponade or subacute effusive pericarditis.

M mode echocardiography is helpful in the noninvasive evaluation of constriction after cardiac surgery, but it is not clearly diagnostic considering the usual abnormalities of septal motion after such surgery and the lack of a definitive pattern in constrictive pericarditis unrelated to surgery.[27] Nevertheless, the presence of marked pericardial thickening or a posterior pericardial effusion, or both, raises the index of suspicion for postoperative constriction.

The most reliable diagnostic test to document constriction after cardiac surgery was right and left heart catheterization. The basic hemodynamic patterns of this entity are similar to the classic constrictive hemodynamics defined by Shabetai et al.[28] In some cases, the variable degrees of dominant x and y descents in the pressure tracing and the contour of the right ventricular and left ventricular early diastolic dip suggest a less rigid form of constriction similar to Hancock's fibroelastic or seroeffusive constriction,[13,14] although modified by factors of an open pericardium and previous surgery.

Therapy: A degree of caution should be instituted when clinical data point to constrictive pericarditis after cardiac surgery. Restrictive cardiomyopathy may easily mimic pericardial constriction.[29] The differentiation between the two is often difficult and sometimes may only be resolved by surgical evaluation. Nevertheless, if enough evidence is present to suspect pericardial constriction, aggressive and definitive therapy should be implemented.

Unless contraindicated, an initial medical regimen of diuretic drugs and steroids or anti-inflammatory agents seems warranted. Diuretic drugs may facilitate resorption of fluid in the pericardial space and steroids may reduce the inflammatory response. A response to this therapy may indicate a reversible seroeffusive variation of constrictive pericarditis. The patient should be evaluated frequently and, if symptoms and signs do not recur, therapy should gradually be tapered and discontinued if possible.

If the patient fails to respond to medical therapy and constrictive findings persist, surgical intervention is indicated. If pathologic findings of constrictive pericarditis are found, a radical pericardiectomy should be performed. Although this is an extensive operation, great care should be taken to remove completely the parietal and visceral pericardium.[30,31] and evacuate any loculated hematoma to obtain optimal benefits.

Conclusions: Contrary to previous beliefs, constrictive pericarditis may develop as a complication of cardiac surgery despite an open pericardium. In this study, the incidence rate was 0.2%. Certain clinical and hemodynamic aspects of this entity suggest an elastic form of constriction with reversible and irreversible elements. The development of pericardial constriction after cardiac surgery is not a single pathophysiologic model, but represents a wide clinical spectrum with variable therapeutic responses. Constrictive pericarditis should be considered in the differential diagnosis of patients who, after cardiac surgery, present with cardiac decompensation dominated by right-sided symptoms and signs.

Increased Physical Activity: A Protective Factor Against Heart Attacks in Puerto Rico

MARIO R. GARCIA-PALMIERI, MD, RAUL COSTAS, Jr., MD, MERCEDES CRUZ-VIDAL, MD, PAUL D. SORLIE, MS, and RICHARD J. HAVLIK, MD, MPH

The incidence and potential risk factors of coronary heart disease were assessed in 2,585 rural and 6,208 urban men, aged 45 to 64 years, participating in the Puerto Rico Heart Health Program, a prospective epidemiologic study of coronary heart disease initiated in 1965. An index of daily physical activity and a metabolic equivalent of heaviest activity were estimated from each individual history. Rural men had higher mean levels of overall activity as well as higher levels of heavy activity than urban men. An 8¼ year follow-up study for coronary heart disease other than angina pectoris was analyzed for relationships with physical activity. Significant inverse associations were found for both urban and rural men. Metabolic equivalent of heaviest activity showed similar results. Although the physical activity index was inversely associated with most known coronary risk factors, multivariate analyses indicated that a significant independent inverse relationship existed with the incidence of coronary heart disease. In Puerto Rico, increased physical activity appears to be a separate protective factor against heart attacks.

The status of physical activity as a protective factor against coronary heart disease continues to be evaluated by epidemiologists and clinical investigators. A recent report from Framingham[1] suggests an inverse relationship between usual physical activity assessed at baseline and the subsequent development of coronary heart disease within 14 years. In contrast to the mainland United States, where a sedentary life-style is almost universal, rural Puerto Ricans are much more involved in regular physical activity. This higher activity level in rural men very likely represents occupation-related activities such as farming and cutting sugar cane. Furthermore, in the hilly rural area where access to roads is limited, the daily activities of living require a considerable amount of strenuous walking. This situation provides more variability in exercise level within a population and has analytical advantages.

The Puerto Rico Heart Health Program originated in 1965 and has followed up a group of 8,793 men, aged 45 to 64 years, for incidence of coronary heart disease.[2] An early report from this study,[3] with 2½ years of follow-up, gave equivocal results as to the importance of physical activity as a predictor of subsequent coronary heart disease. The availability of 8¼ years of follow-up data provides a better opportunity for a detailed analysis of this important question.

Methods

Study group: The Puerto Rico Heart Health Program is a prospective epidemiologic study of coronary heart disease in urban and rural men aged 45 to 64 years when determined in 1965.[2] An enumeration of all men of these ages living in 3 urban and 4 rural areas in the northeast part of Puerto Rico was conducted by the personnel who participated in the United States decennial census. The urban group consisted of those areas in 3 *municipios* (municipalities) in the metropolitan area of San Juan with housing clusters of 25 or more dwelling units. The rural group consisted of the hilly farming

areas of 4 *municipios* located up to 35 miles from San Juan. All of these men were encouraged to attend the baseline examination, and an 80% response rate was achieved. At examination, men of other ages (35 to 44 and 65 to 79 years) who had been inappropriately included in the enumeration were accepted, and the total number of examined men was 9,824.

At the initial examination, each participant provided sociodemographic information and a medical history and had a physical examination with laboratory determinations and a resting 12-lead electrocardiogram. At this 1st examination, 2,585 rural and 6,208 urban men aged 45 to 64 years were assessed for physical activity status. Only 36 had an incomplete history. All persons were evaluated with cardiovascular examinations at 3 subsequent periods, the last being 8¼ years from the initial examination. Participation in the reexamination included about 90% of survivors, and those not appearing for examination were followed up for vital status. Diagnosis of coronary heart disease was made according to predetermined criteria.[2] For example, criteria for myocardial infarction included prolonged chest pain and pathologic Q waves or evidence of muscle necrosis by enzyme studies, or both. The classification of coronary disease other than angina pectoris (heart attacks) included sudden and nonsudden coronary heart disease death, myocardial infarction, and coronary insufficiency, but not angina pectoris.

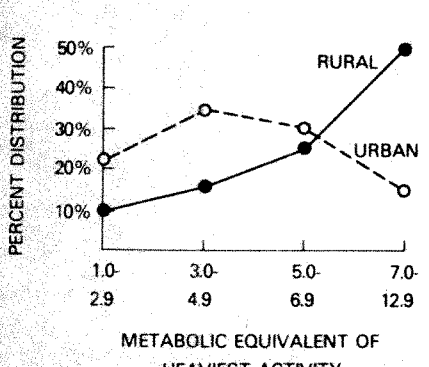

FIGURE 1. Percent distribution of metabolic equivalent of heaviest activity, by area, in men aged 45 to 64 in the Puerto Rico Heart Program.

At the initial examination and subsequently at 2 follow-up examinations, usual 24 hour physical activity was assessed. The number of hours of rest and sleep as well as of occupational, leisure, and other activities were ascertained. These activities were classified as sedentary, slight, moderate, and heavy. A weighting factor for each level of effort was multiplied by the number of hours engaged in the activity, and these were added to give a physical activity index. The weighting factors for sleep and for sedentary, slight, moderate, and heavy activity were 1.0, 1.1, 1.5, 2.4, and 5.0, respectively.[2] The questionnaire and the weighting factors were patterned after those of the Framingham Study. The weighting factors somewhat approximate the oxygen consumption for each of these activities.[1]

In addition, each individual was asked to identify the heaviest activity lasting at least 2 hours per week. A set of metabolic equivalents derived from the literature[4] was applied to these occupational or leisure time activities. The metabolic equivalent is the ratio between energy expenditure of the activity and the basal state. The heaviest activity was then characterized by this metabolic equivalent.

Statistical analysis: The logistic function model was used to analyze the relationships between physical activity and the clinically manifest incidence of coronary heart disease for univariate and multivariate situations, and coefficients were estimated by the maximal likelihood method.[5] If the ratio (z) between the regression coefficient and its standard error is greater than 1.96, the coefficient is statistically significant at the $p < 0.05$ level.

Results

Physical activity and metabolic equivalent indexes: As a measure of the repeatability of the assessment of physical activity, between-examination correlation coefficients of the indexes were calculated. Physical activity was measured at 3 successive examinations 2½ to 3 years apart. The physical activity correlations are between 0.30 and 0.59 depending on the area and examination pair. For comparison, except for fairly stable measurements such as height and weight,

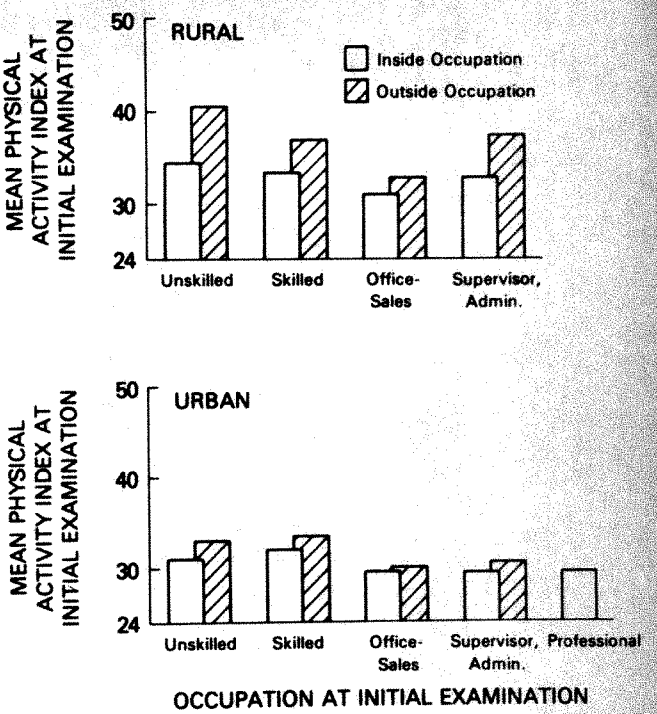

FIGURE 2. Age-adjusted mean value of physical activity by levels of occupation, in men aged 45 to 64 years free of coronary heart disease.

the between-examination correlation of systolic blood pressure is among the largest obtained and ranges from 0.64 to 0.72. Although the reliability of physical activity assessment is of concern, the between-examination correlations suggest reproducibility from 1 examination to the next. The between-examination correlations of metabolic equivalent are similar to those of the physical activity index. Although physical activity assessment addresses usual overall activity and the metabolic equivalent addresses heaviest activity, these 2 indexes are highly correlated with each other (r = 0.63 for rural; r = 0.55 for urban).

The mean values of physical activity differ considerably by age and area of residence (Table I). The residents of rural areas have higher average levels of physical activity index and metabolic equivalent of highest activity than do urban subjects. There is a slight trend toward less physical activity in the older subjects.

The distribution of metabolic equivalent of heaviest activity (metabolic equivalent) (Fig. 1) shows that almost 50% of the men in the rural area have a metabolic equivalent level of 7 or more. This figure indicates that they engage in an activity of at least metabolic equivalent 7 for a total of at least 2 hours a week. A level of 7 or more can be achieved by activities such as moving heavy objects of 30 kg (65 pounds) or more, shoveling, or cutting sugar cane.

Physical activity index shows a relationship with occupational classification, particularly in rural areas (Fig. 2). Persons whose principal job location is out-of-doors show higher mean levels of activity than do those with indoor occupations.

Unskilled and skilled workers show higher levels than do those with more sedentary occupations such as office work. The high level of physical activity in the rural supervisor class, that is, the owner of a farm, is worth noting. Although he may not directly work the farm, he may be involved in a variety of activities, such as walking or climbing hills to supervise his workers, which would result in a higher index. These expected associations with occupation add credibility to the use of the physical activity index as a measure of activity.

Association with other factors: Product moment correlation coefficients were calculated between physical activity index and a variety of other characteristics measured at the initial examination (Table II). Heart rate stands out as the variable most strongly correlated with physical activity. The sign is negative, indicating that greater physical activity is associated with decreased heart rate. It also provides credibility of the physical activity index as a measure of physical activity because the hallmark of a cardiovascular response to physical training is resting bradycardia. As further confirmation of the higher exercise levels in this population, 23.4% of the rural and 10.7% of the urban men have a resting heart rate below 60 beats/min. In general, physical activity correlates in a beneficial way with most of the usual risk factors for coronary heart disease. A higher physical activity index is associated with decreased blood pressure, relative weight, and serum cholesterol level; however, these correlations are generally small.

Relationship with coronary heart disease: Physical activity is inversely associated with the 8¼ year incidence of coronary heart disease other than angina pectoris (Fig. 3). This association is statistically dif-

FIGURE 4. Incidence of coronary heart disease (CHD) other than angina pectoris (AP) by metabolic equivalent of heaviest activity; age-adjusted 8¼ year rates, in men aged 45 to 64 years.

ferent from zero and shows that the highest incidence of coronary heart disease, other than angina pectoris, is found in men in the lowest physical activity group. A point of minimal risk appears at level 36 to 44 and a slight increase in risk at highest level of physical activity. The range of risk is twofold from the lowest to the highest. The index of 36 to 44 could be approximated by the sum of 8 hours of sleep, 8 hours of sitting, and 8 hours of walking. The population at risk indicates that there are adequate numbers at each level of activity, and these numbers are slightly lower than the totals found in Table I, because the population at risk is free of existing coronary heart disease.

Physical activity is not related to the incidence of angina pectoris (Table III). Age-adjusted standardized logistic function coefficients show no apparent significant relationship for angina pectoris. The coefficients for coronary heart disease other than angina pectoris are statistically significant, with a lower incidence in the physically active group.

Incidence of coronary heart disease other than angina pectoris is also associated with the metabolic equivalent (Fig. 4). This figure does not show the upturn in incidence for those who engage in very heavy activities, although a slight increase is observed in the next lower group. Using the logistic function, the age-adjusted trends for rural and urban groups are statistically significant.

The activity index used in this study is a composite of the number of hours spent at varying levels of activity. It is of interest whether any specific activity is associated with the risk of coronary heart disease. Because the number of hours of sleep and sedentary, slight, moderate, and heavy activity must add up to 24, these activities are correlated with each other. The number of hours of sleep and sedentary activity are negatively correlated with the amount of moderate and heavy activity. The association of the number of hours of each activity with coronary heart disease other than angina pectoris is shown in Table IV. Increased duration of sleep is associated with a higher incidence of coronary heart disease other than angina pectoris, whereas higher levels of moderate and heavy activity are associated with a lower incidence.

Correcting for related factors: Multivariate analysis attempts to determine whether the observed association is merely a result of the association of physical activity with other known risk factors. The coefficients of the multiple logistic function are shown in Table V. Even when the other specified factors are taken into account, physical activity contributes independently to the risk of coronary heart disease other than angina pectoris. When both the hours of sleep and hours of heavy activity are entered simultaneously into the multivariate equation and the physical activity index is removed, neither of these 2 components reach independent significance. This finding suggests that the physical activity index, which is the weighted sum of different activity levels, is more closely associated with coronary heart disease than with any of the separate activity levels themselves.

One factor that may be a confounding variable and that cannot be quantified adequately, is coexisting disease; for example, is low physical activity an individual's response to existing ill health rather than a promoter of poor cardiovascular health? The analysis of incidence in this report was calculated for a period of 8¼ years and used a base population free of definite or questionable clinically evident coronary heart disease. Thus, at the time of assessment of physical activity, the population analyzed did not have clinically recognized coronary disease. Additionally, the analysis in Table V was made excluding events in the first 2½ years after the

Heavy activity	−0.312	−2.34	−0.145	−1.86

physical activity measurement. By excluding these early cases, we most likely eliminated those individuals whose low level of physical activity could have been a response to serious ill health, leaving the remaining cases less affected by this phenomenon. The results were essentially the same, although in the urban area the slope for physical activity was slightly lower. There is a significant independent association (inverse) between physical activity index and incidence of coronary heart disease other than angina pectoris, indicating that existing disease may be partly, but not completely, responsible for the observed association.

Discussion

Comparison with the Framingham Study: Findings from an 8¼ year follow-up study of the Puerto Rico cohort are generally consistent with those of other reported epidemiologic studies.[6–11] A significant inverse multivariate relationship was found in the prospectively studied Framingham population.[1] Although the same physical activity questionnaire was used in both locations, no strict comparative studies were performed. Nevertheless, the mean levels in Framingham and urban Puerto Rico are similar, whereas, as expected, the rural Puerto Rican men have higher activity scores. When the relative magnitude of standardized multivariate logistic coefficients in the 2 studies is compared, physical activity index in Framingham is 5th behind systolic blood pressure, cholesterol, cigarettes, and age.

TABLE V Multiple Logistic Function Coefficients: Risk of Coronary Heart Disease Other Than Angina Pectoris Men Aged 45 to 64 Years; Puerto Rico Heart Health Program, 8¼ Year Follow-Up Study

Independent Variables	Standardized Multiple Coefficients			
	Rural		Urban	
	Coefficient	z Statistic	Coefficient	z Statistic

Heart rate	0.024	0.22	0.013	0.20
Serum cholesterol	0.114	1.05	0.252	4.48
Cases (n)/cases at risk (n)	81/2,389		254/5,766	

Among rural Puerto Rican men, the physical activity index is 2nd behind only blood pressure in predicting subsequent heart attack. This finding suggests that in a low-incidence setting where there is a wider range of physical activity, increased physical activity may have more detectable effects. The relative risk, approximated by relative odds, for a 10 unit difference in physical activity index is about 1.3 in rural Puerto Rico, a value comparable to that found in Framingham.

Comparison with other studies: In at least 3 other United States populations[12–14] and in Sweden,[15] a consistent relationship with physical activity was not detected. These studies primarily used estimates of physical activity associated with occupation. Other occupation-based studies, including those of busmen[6] and longshoremen,[9] show a relationship. It is possible that in certain industrial situations, the difference in job-related activity is minimal, and greatest variation is found in leisure time activities. In a Belgian study, gardening, cycling, and walking on a regular basis were protective factors against coronary heart disease.[16] In a case-control retrospective study, leisure activity was more protective against death than was job-related activity. In the Puerto Rico study leisure activities were not separated from occupational activities in the final estimate of the physical activity index or metabolic equivalent of maximal 2 hour effort.

In the Puerto Rico study there was no threshold of physical activity at which the incidence of coronary attacks increased abruptly. The existence of such a critical level has been hypothesized.[17] However, above a score of 44, there was a slight upturn in incidence, resulting in some suggestion of a J-shaped relationship (Fig. 3).

The increased incidence of coronary attacks among those urban men with an index above 44 may be confounded with cigarette smoking. When the data for Figure 3 were analyzed for cigarette smokers and nonsmokers separately, a steady decreasing incidence with increased activity was seen for nonsmokers. Cigarette

smokers showed a decreasing incidence until level 45 to 71, where the incidence increased to the same level as that of the least physically active group. Although this result should be viewed with caution because of the small number of active urban men, the implication is that high physical activity is not as beneficial in cigarette smokers. There have been a few reports[18] of occupations with high intensity activity being associated with increased cardiovascular risk.

Physical activity and coronary atherosclerosis: Some investigations, however, suggest that physical activity may contribute more to preventing death, especially sudden death, than having an effect on total incidence through decreasing the amount of atherosclerosis.[9] In Puerto Rico, the relationship is similar whether heart attacks or coronary heart disease deaths are used separately as end points. The percentage of fatal heart attacks is comparable for those with high or low levels of physical activity. Too few sudden deaths have occurred in this cohort to permit meaningful analysis.

Autopsy series, although potentially biased in unknown ways, provide some additional information. No relationship between physical activity and mural atherosclerosis was found by Morris and Crawford,[19] although a relationship did exist between coronary occlusion and the number of myocardial lesions. Spain and Bradess,[20] using information concerning premortem occupation, found an apparent inverse relationship between the degree of atherosclerosis and the level of physical activity. Autopsy results from the Puerto Rico study show a trend, although nonsignificant, towards a relationship between greater levels of physical activity and decreased coronary atherosclerosis.[21]

Assessment of physical activity: The measurement tool used in this study was developed by Framingham Heart Study personnel. It suffers from the potential problem of both the interviewer's bias entering into the final scoring of the index and the inaccurate recall by the subject. Other sensitive, detailed, and potentially more accurate instruments have been developed after the start of the Puerto Rico Study.[22] In this study, an additional measure of physical activity was used, namely, the metabolic equivalent of the most intense activity. This value is strongly correlated with the physical activity index, and not surprisingly, results are similar with both measures of physical activity.

To differentiate the important components of physical activity under the separate effects of basal activities of sleep and rest versus heavy levels of activity, both of these activities were entered simultaneously into a multivariate logistic calculation. In this situation, neither component of activity was strongly significant, suggesting that it was the interrelated blend of activities that was most important.

Cause or effect: A recurrent concern among investigators considering the physical activity question is the potential problem of differentiating between selective factors and protective ones. After the first study of Morris et al.,[23] they investigated this aspect in a unique way[6] and found that although selective factors may have been operating, with obese persons choosing the driver jobs more often, they could not explain the entire difference between conductors and bus drivers. In prospective studies using a questionnaire representing current activities, the preclinically identified cardiac patient may reduce his activity. All participants in the present analysis were free of clinically recognized coronary disease at baseline, and the incidence was evaluated over the next 8¼ years. In a further attempt to eliminate any bias, the incidence cases in the first 2½ years of experience were eliminated. The relationship held, although some of the association was presumably accounted for by unknown coronary disease.

Other factors: An attempt was made in the analysis to correct for the other known correlates of physical activity that are potential risk factors for coronary heart disease. Blood pressure, cigarette smoking, cholesterol, heart rate, and relative weight were included in the multivariate analysis, and physical activity remained statistically significant. High density lipoprotein cholesterol, which appears to be elevated with physical activity,[24] was measured only in a pilot study; and platelet stickiness, fibrinolysins, and other hematologic factors were not measured in this study. In addition, no direct measures of emotional "stress" were made in this population. If occupational class is considered as a rough measure of possible increased job pressure, physical activity has a comparable inverse relationship with the incidence of heart attack in each of the occupational categories. Therefore, it is doubtful that our results can be explained in a bias due to "stress" being greater and physical activity being less in 1 subgroup compared with another.

Implications: The notion that physical activity may be protective against heart attacks has gained in popularity, and has resulted in recommendations, using mass media, to get people interested in exercise, group and personal incentives to maintain interest, and the provision of special places to exercise.[25] This physical activity hypothesis, however, has not been adequately tested with appropriate clinical trials.[26]

The Puerto Rico study, a prospective epidemiologic investigation, supports previous studies that increased physical activity may protect against coronary heart disease. This observation has been extended to a low incidence area, where the rate of heart attacks is about half that of the mainland. The benefits from the higher activity levels in Puerto Rico probably reflect a lifetime pattern of steady activity rather than a recent increase in exercise.

Inter- and Intraatrial Dissociation During Spontaneous Atrial Flutter: Evidence for a Focal Origin of the Arrhythmia

PETER L. FRIEDMAN, MD, PhD,* PEDRO BRUGADA, MD, KARL-HEINZ KUCK, MD, DENIS ROY, MD, JERONIMO FARRE, MD, FRITS W.H.M BÄR, MD, and HEIN J.J. WELLENS, MD

Programmed electrical stimulation of the heart was performed in 2 patients with spontaneous atrial flutter. Patient 1 was a young man with paroxysmal atrial flutter that had proved resistant to drug therapy and who was studied during an episode of sustained flutter. In this patient rapid atrial pacing from the coronary sinus at a critical rate faster than the intrinsic flutter rate provoked local atrial fibrillation in the mid and low right atrium which persisted after termination of pacing. In spite of persistent local fibrillation in these regions, atrial flutter continued in the left atrium and the high right atrium. A second burst of pacing resulted in restoration of sinus rhythm. Patient 2 was an elderly woman with probable sick sinus syndrome who developed spontaneous atrial flutter during the course of an electrophysiologic investigation. During flutter intracavitary recordings from multiple sites in the atria revealed a pattern of 3:2 Wenckebach conduction between the left atrium and the high right atrium, with block of every third atrial depolarization at the latter site. These results indicate that atrial flutter may exist at some sites in the atria which are functionally dissociated from the remainder of the atrial tissue, thus supporting the hypothesis that flutter in some patients may be focal in origin.

The electrophysiologic mechanism of atrial flutter in human beings has long been a matter of controversy. Some authors[1,2] have suggested that atrial flutter is due to circus movement which incorporates a large mass of atrial myocardium. An opposing view is that atrial flutter is basically focal in origin, arising in a small functionally circumscribed area of tissue.[3–5] Recently, utilizing programmed electrical stimulation of the heart, we had the opportunity to study 2 patients with spontaneous atrial flutter in whom flutter existed in a part of the atria functionally dissociated from adjacent areas. Since these observations suggest a focal origin of the arrhythmia, we report the results obtained in these patients in detail.

Methods

Patients: Patient 1 is a 30 year old man with no demonstrable structural heart disease who first developed paroxysmal atrial flutter 2 years earlier. Despite therapy with digoxin, quinidine sulfate, disopyramide phosphate, and amiodarone, either singly or in combination, the paroxysms of atrial flutter continued, culminating in an episode of sustained atrial flutter which required hospital admission.

Patient 2 is a 71 year old woman with a history of mild hypertension, stable angina pectoris, and sick sinus syndrome, characterized by periods of sinus bradycardia alternating with paroxysmal atrial fibrillation and supraventricular tachycardia. Because of excerbation of angina during tachycardia and at least 1 syncopal episode, she was referred to our hospital for further evaluation.

Electrophysiologic study: Both patients underwent electrophysiologic investigation in the postabsorptive, nonsedated state. Patient 1 was receiving amiodarone, 400 mg by mouth daily, at the time of study. Patient 2 had had no antiarrhythmic drugs for 24 hours before the study. After in-

formed consent was obtained, the patients were taken to the cardiac catheterization laboratory where, using the Seldinger technique, electrode catheters were passed through both femoral veins and positioned in the heart under fluoroscopic guidance. These included quadripolar catheters in the right atrium and coronary sinus, a bipolar catheter in the right ventricular apex, and a bipolar catheter placed across the tricuspid valve for recording the His bundle electrogram.

The methods for stimulation and recording used in our laboratory have previously been described in detail.[6] In brief, in the presence of sinus rhythm refractory periods were determined using the single test stimulus method during basic drive pacing of the atrium and ventricle at each of several basic cycle lengths. During atrial flutter the effects of single or multiple atrial premature depolarizations on the time relations of the tachycardia were studied first. This was followed by bursts of rapid atrial pacing at progressively decreasing pacing cycle lengths in an attempt to terminate tachycardia. In addition, Patient 2 received an infusion of procainamide, 600 mg intravenously over 6 minutes, in order to study the drug's effectiveness in terminating flutter.

Results

Patient 1

Atrial recordings during flutter (Fig. 1): Atrial flutter with a 4:1 A-V relationship was present at the beginning of the electrophysiologic investigation. The flutter waves in the inferior electrocardiographic leads demonstrated an initial negative followed by a positive deflection as in flutter of the so-called common type. Examination of bipolar atrial electrograms from multiple sites revealed an atrial rate of 260/min (cycle length 230 ms) that varied slightly, the minimum and maximum cycle lengths being 220 and 250 ms, respectively. Earliest atrial activity was present in the low right atrial septum in the region of the His bundle recording site and corresponded to the beginning of the flutter waves in the surface electrocardiogram. Atrial activity next appeared in the proximal coronary sinus, followed by nearly simultaneous activation in the distal coronary sinus as well as the high and mid right atrium (high right atrium not shown). The atrial electrogram recorded from the mid right atrium appeared somewhat broad and fragmented in comparison with the sharper, more discrete electrograms recorded at other sites. However, at all sites the recordings between successive electrograms were isoelectric, without any evidence of continuous electrical activity (Fig. 1).

Single atrial extrastimuli were ineffective in terminating atrial flutter, regardless of their degree of prematurity or the site at which they were delivered. These extrastimuli either evoked no response or were followed by only local early depolarization and then a fully compensatory pause. Depolarization at other more distant sites occurred when expected, the flutter continuing at the same rate and with the same atrial activation sequence. Similarly, 2 or 3 consecutive atrial extrastimuli did not interrupt or alter the arrhythmia.

Rapid atrial pacing (Fig. 2): During rapid atrial pacing at rates slightly faster than the flutter rate (cycle length 170 to 200 ms), all atrial recording sites were depolarized at the pacing rate and the atrial activation sequence was different from that during flutter, earliest activity now occurring in the distal coronary sinus (near the pacing site), followed by the His bundle region and then the high and mid right atrium nearly simultaneously. This was reflected in the surface electrocardiogram by flutter waves of lower amplitude which had a small initial positive component. The atrial electrograms in the mid right atrium and His bundle region during pacing at these rates appeared broader and more fragmented than during atrial flutter. When the pacing train of stimuli was stopped, atrial flutter reappeared in the first postpacing cycle. The atrial activation sequence and flutter rate after pacing at these rates were identical to those before the pacing train. During atrial pacing at a more rapid rate (cycle length 160 ms) the atrial electrograms recorded in the mid right atrium and His bundle region demonstrated irregular, continuous electrical activity spanning the entire interval between pacing

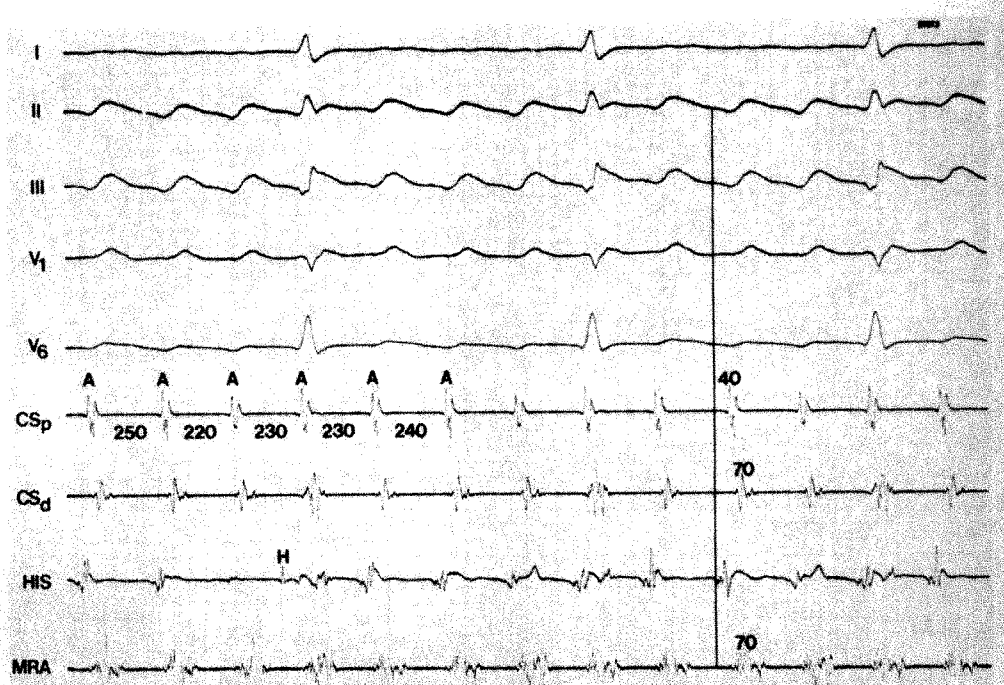

FIGURE 1. Patient 1. Simultaneous recording of **(top to bottom)** electrocardiographic leads I, II, III, V_1, and V_6, as well as electrograms from the proximal coronary sinus (CS_p), distal coronary sinus (CS_d), His bundle region, and mid right atrium (MRA) during spontaneous atrial flutter. The atrial cycle length varies between 220 and 250 ms. **Vertical line at right** marks the beginning of the flutter wave in lead II with corresponding activation times at each atrial recording site as indicated. Earliest atrial activity appears in the His bundle recording site. Note the stable isoelectric baseline between successive atrial electrograms at each recording site.

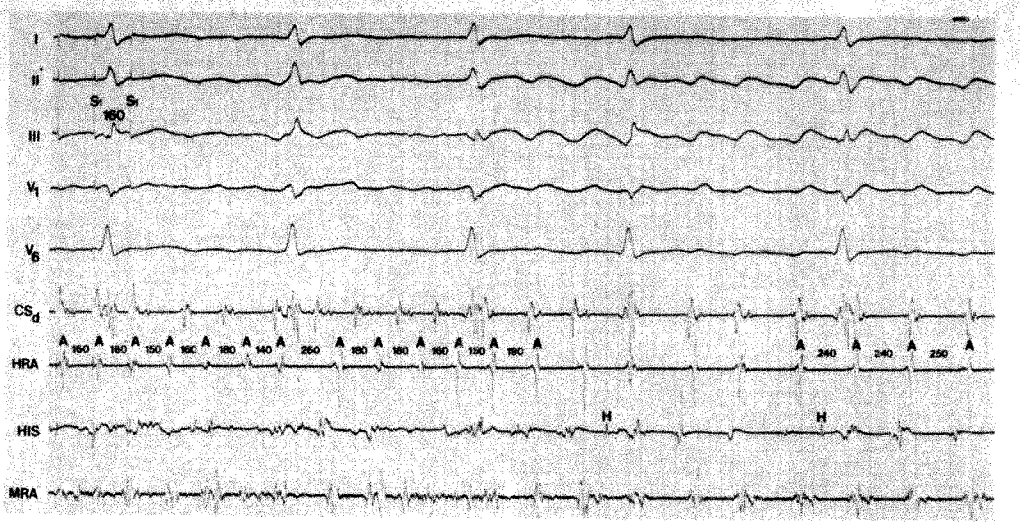

FIGURE 2. Patient 1. Simultaneous recording of (**top to bottom**) electrocardiographic leads I, II, III, V_1 and V_6, as well as electrograms from the distal coronary sinus (CS_d), high right atrium (HRA), His bundle region, and mid-right atrium (MRA) during and immediately after a burst of pacing from the coronary sinus at a cycle length (S_1–S_1) of 160 ms. The last 3 paced beats of the pacing train are shown on the **left**. After termination of pacing there is fragmented, continuous electrical activity in His bundle region and mid-right atrium. Atrial electrograms at the other 2 sites remain discrete, with isoelectric baselines separating successive atrial deflections. Immediately after pacing there is transient overdrive acceleration of flutter, as determined by the rate of depolarization in the coronary sinus and high right atrium. As local fibrillation in the mid-right atrium and His bundle recording sites disappears, the rate of flutter returns to that present before pacing.

stimuli, consistent with local fibrillation. In contrast, electrograms from the high right atrium and distal coronary sinus continued to show regular, discrete deflections after each pacing stimulus. After termination of pacing at this rate, transient overdrive acceleration of flutter was noted, manifested by repetitive, discrete, slightly irregular, flutter-like electrograms in the high right atrium and distal coronary sinus at a rate faster than the intrinsic flutter rate before pacing. The continuous electrical activity recorded in the mid right atrium and His bundle region also persisted transiently after pacing. The surface electrocardiogram at this time did not show discrete flutter waves, but instead resembled typical atrial fibrillation. Gradually, the continuous electrical activity in the mid and low right atrium became more organized; this was associated with slowing of the flutter rate back to the intrinsic rate present before pacing and the reappearance of typical flutter waves.

During a 15 second burst of atrial pacing at a cycle length of 150 ms (Fig. 3), similar observations were made as during pacing at a cycle length of 160 ms. However, after this burst overdrive acceleration in the distal coronary sinus and high right atrium was persistent rather than transient, accompanied by persistent continuous electrical activity in the mid- and low right atrium as well as the electrocardiographic appearance of atrial fibrillation. After several minutes of this persistent overdrive acceleration, a second burst of atrial

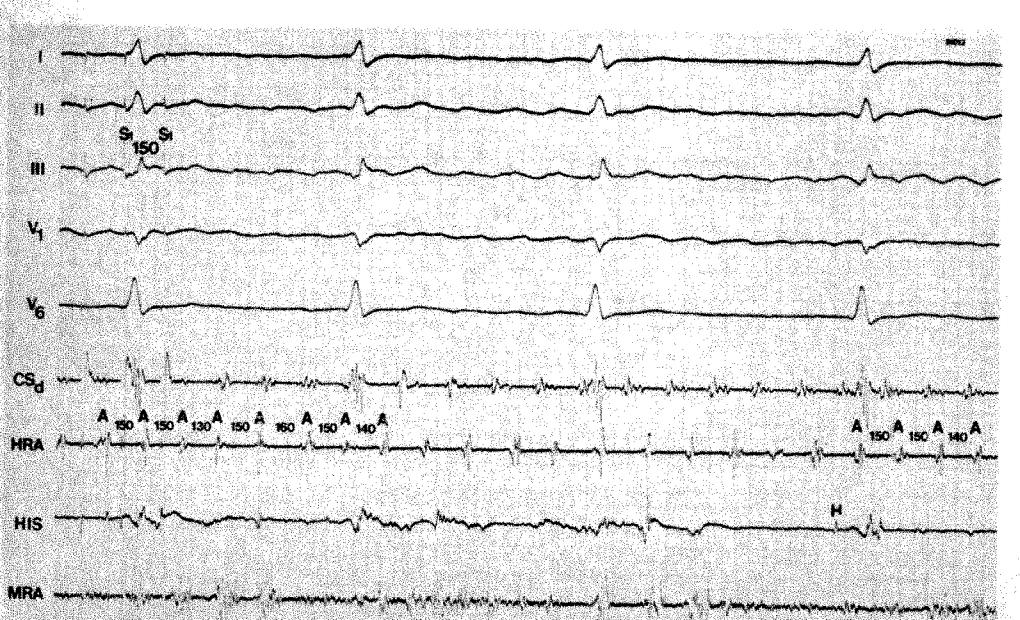

FIGURE 3. Patient 1. Same organizations of tracings as in Figure 2 during the rhythm immediately after a burst of atrial pacing from the distal coronary sinus (CS_d) at a cycle length (S_1–S_1) of 150 ms. The last 3 paced beats of the pacing train are shown on the **left.** Continuous, fragmented electrical activity is present in the mid right atrium (MRA) and His bundle region during pacing and persists after termination of pacing. This is associated with persistent postpacing overdrive acceleration of flutter in the high right atrium (HRA) and coronary sinus. This overdrive acceleration of flutter was still present 2 minutes after termination of pacing. Note the appearance of atrial fibrillation in the surface electrocardiogram after pacing has stopped.

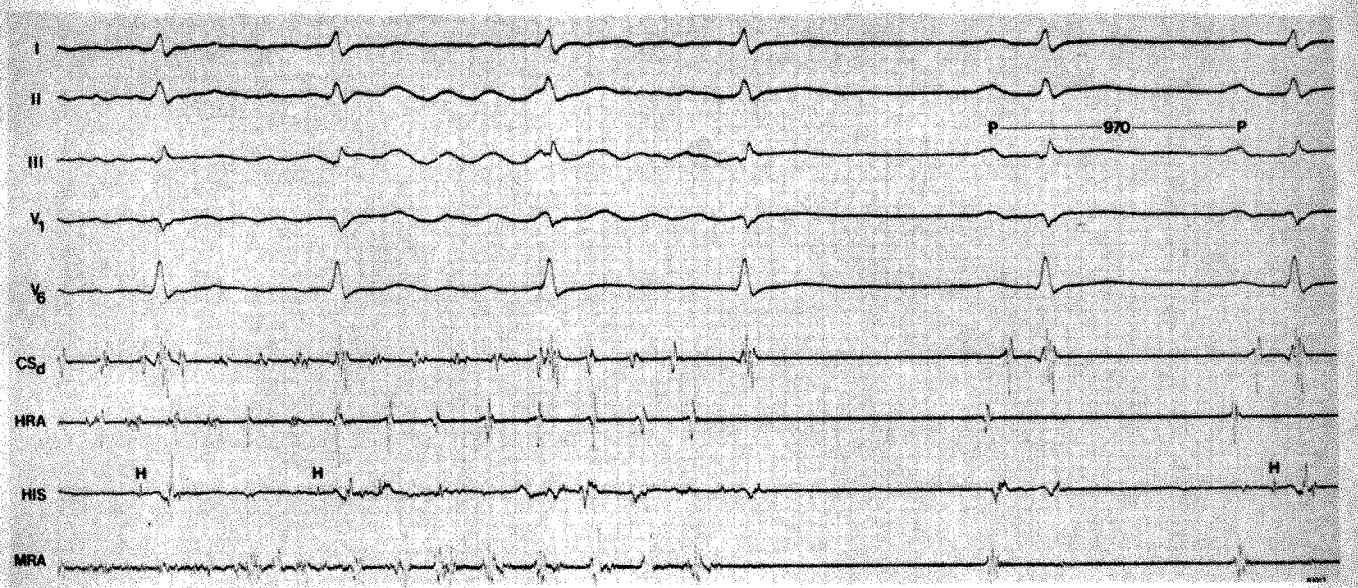

FIGURE 4. Patient 1. Same organization of tracings as in Figures 2 and 3. A second burst of atrial pacing at a cycle length of 150 ms was applied (not shown) after the records shown in Figure 3. The records shown here followed this second burst of pacing. As before, pacing was followed by local fibrillation in the mid-right atrium (MRA) and His bundle region and overdrive acceleration of flutter in the high right atrium (HRA) and distal coronary sinus (CS_d). The surface electrocardiogram at this time showed atrial fibrillation (**left**). Organization of local fibrillation in the mid-right atrium and His bundle region then occurred, associated with slowing of the flutter rate in the high right atrium and coronary sinus and a reappearance of flutter waves in the surface electrocardiogram. This was quickly followed by a return to sinus rhythm (**right**).

pacing at a cycle length of 150 ms was applied. Immediately after this second period of pacing, the overdrive acceleration was still present (Fig. 4). However, local fibrillation in the mid and low right atrium gradually organized into discrete electrograms, concomitant with slowing of the flutter rate at other sites and a reappearance of flutter waves in the surface electrocardiogram. This was followed by an abrupt return to sinus rhythm (Fig. 4). Atrial flutter could not be reinitiated by either single or multiple atrial premature depolarizations, regardless of their degree of prematurity or site of origin.

Patient 2

Atrial recordings during flutter (Fig. 5): Although sinus rhythm was present at the beginning of the study, sustained atrial flutter was provoked by a spontaneously occurring atrial premature depolarization. The atrial flutter was characterized by a rate of 340/min (cycle length 175 ms between successive atrial waves recorded in the coronary sinus), and a 2:1 A-V relationship and flutter waves in the surface electrocardiogram that were predominantly negative in the inferior leads. The atrial activation sequence during flutter revealed earliest activity appearing nearly simultaneously in the coronary sinus and low right atrium in the region of the His bundle, followed by later activation of the high right atrium. At the former two recording sites the interval between successive atrial waves was 175 ms and quite constant. In contrast, atrial electrograms recorded from the high right atrium demonstrated a regularly irregular, repeating pattern. Careful inspection revealed that this was due to progressive delay in conduction between the coronary sinus and the high right atrium, with conduction block of every third impulse at the latter site. The pattern of conduction between these 2 sites demonstrated Wenckebach periodicity.

Intravenous administration of 600 mg of procainamide resulted in a slowing of the atrial flutter rate to 285/min (cycle length 210 ms), as measured by successive atrial waves recorded in the coronary sinus. During procainamide infusion, conduction block between the coronary sinus and the high right atrium became variable, sometimes showing a 3:1 pattern and at other times a 4:3 or 5:4 Wenckebach periodicity. Thirty minutes after completing the drug infusion the rhythm spontaneously reverted to sinus rhythm.

Discussion

Mechanisms of atrial flutter: Controversy regarding the mechanism of atrial flutter in human beings has centered around 2 divergent views. One of these holds that the arrhythmia is due to circus movement which incorporates most or all of the atrial myocardium as the reentrant pathway.[1,2] Other investigators[3–5] have felt that a focal origin, whether the result of reentry, enhanced automaticity or triggered activity, is more likely. Experimental studies[7–9] in isolated rabbit atrial muscle suggest that, although circus movement may well be the underlying mechanism, the reentrant pathway is in fact as small as physiologically possible, determined predominantly by the constraints of atrial refractoriness. Because the reentrant circuit is so small in this model, atrial flutter arising by such a mechanism can be thought of as basically focal in origin. Many clinical studies[10–12] utilizing programmed electrical stimulation of the heart tend to support this view.

Focal origin of atrial flutter with interatrial conduction delay: Both patients in the present study demonstrated interatrial dissociation or conduction delay phenomena during spontaneous atrial flutter which suggested that a significant portion of the right atrium was not essential for maintenance of the arrhythmia. This observation, therefore, supports the notion of a focal origin of atrial flutter. In Patient 2, for example, multiple intracavitary recordings during flutter revealed a 3:2 relation between depolarization in the left atrium (coronary sinus) and in the high right

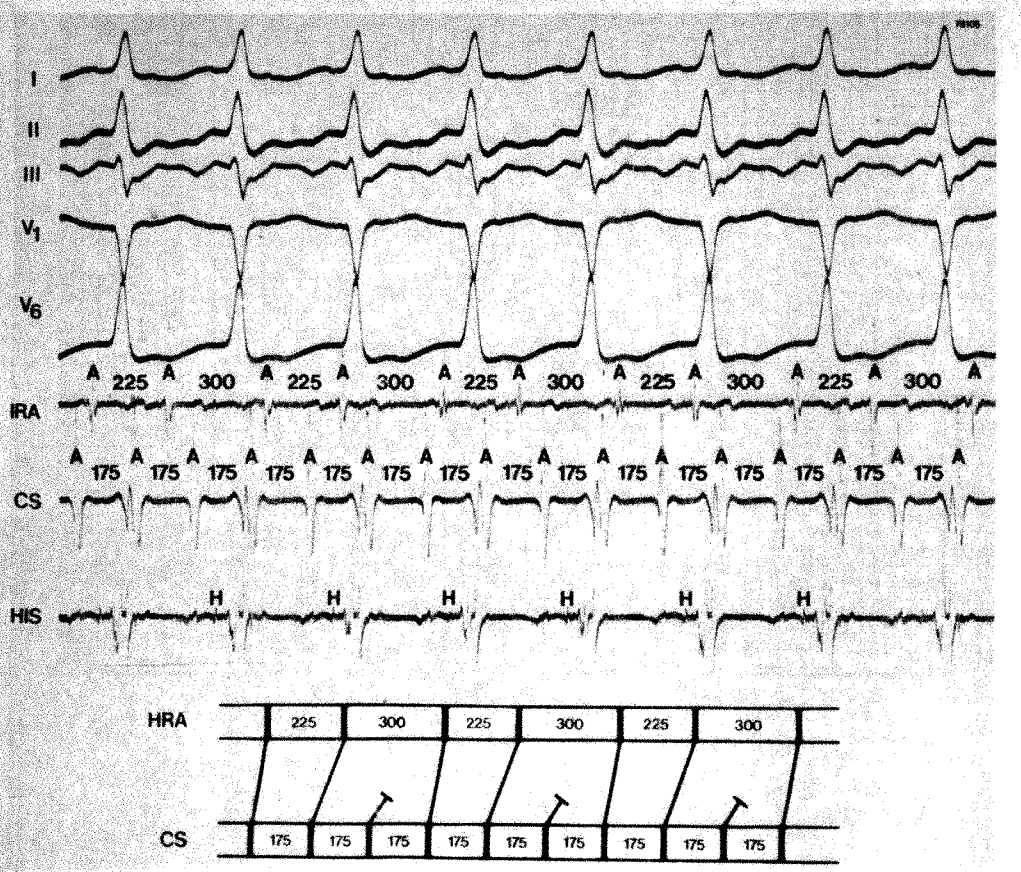

FIGURE 5. Patient 2. **Top panel,** simultaneous recording of **(top to bottom)** electrocardiographic leads I, II, III, V_1, and V_6, as well as electrograms from the high right atrium (HRA), coronary sinus (CS), and His bundle region during spontaneous atrial flutter. The cycle length of atrial depolarization in the coronary sinus is 175 ms and constant throughout, whereas atrial electrograms in the high right atrium occur with a regularly irregular, repeating pattern. The pattern of atrial depolarization in the His bundle region is probably the same as in the coronary sinus, although this is somewhat obscured by the proximity of these electrograms to the local ventricular electrogram. **Bottom panel,** Lewis diagram of atrial depolarization in the coronary sinus (CS) and high right atrium (HRA) during atrial flutter as shown in the **top panel.** 3:2 Wenckebach conduction between the coronary sinus and high right atrium could account for the observed patterns of recorded atrial electrograms.

atrium, the time relations being consistent with 3:2 Wenckebach conduction between the 2 regions. Electrographic atrial deflections recorded from the coronary sinus occurred at a constant rate of 340/min, identical to the rate of the flutter waves in the surface electrocardiogram. Furthermore, the coronary sinus was 1 of the earliest regions activated during flutter. These observations suggest that left atrial tissue in the coronary sinus was an integral part of the focus causing flutter, whereas activation of the high right atrium represented merely passive, variable conduction from the flutter focus. Similar interatrial conduction delay has been reported for paroxysmal atrial tachycardia originating in a left atrial focus.[13,14] Interatrial conduction delay and block have also been reported during atrial flutter in a patient with preexcitation,[15] but this was after intravenous administration of propranolol and it occurred transiently immediately before resumption of sinus rhythm. Sustained interatrial conduction delay during sustained flutter in the absence of drug effect has not been described previously.

Persistent local atrial fibrillation with persistent flutter at other sites: Observations in Patient 1 during spontaneous atrial flutter also suggested a focal origin of the arrhythmia. In this patient rapid atrial pacing at a cycle length of 150 ms resulted in local fibrillation in the mid right atrium and low right atrial septum (His bundle region) which persisted after termination of pacing, whereas recordings from the high right atrium and coronary sinus continued to show discrete, repetitive electrograms typical of flutter (Fig. 3). Since atrial flutter persisted in the high right atrium and coronary sinus even though other areas of the right atrium were fibrillating, clearly these other areas were not essential for maintenance of the flutter. Persistent local fibrillation at some sites with persistent flutter at others is rare.[14,16] One recent report[16] described a patient in whom localized sinus rhythmn was present in the high right atrium, atrial fibrillation in the left atrium, and areas of rapid, regular flutter-like activity at other sites in the right atrium. However, the predominant rhythm in the patient was probably atrial fibrillation in view of the ineffectiveness of both rapid atrial pacing and DC cardioversion to restore sinus rhythm. In our Patient 1 one also might argue that the rhythm present after pacing at a cycle length of 150 ms was, in fact, atrial fibrillation, with only apparent rather than true flutter in the high right atrium and coronary sinus. However, this was demonstrated not to be the case by a second burst of rapid atrial pacing which resulted in a return to sinus rhythm. Reversion to sinus rhythm after rapid atrial pacing is typical of atrial flutter but not atrial fibrillation.

Clinical and therapeutic implications: From a clinical standpoint our observations in Patient 1 are of particular importance since they underscore the limitations of the surface electrocardiogram in defining atrial rhythm. After the first burst of rapid atrial pacing

at a cycle length of 150 ms, this patient's electrocardiogram revealed atrial fibrillation or, at best, flutter-fibrillation, without discrete, regularly repeating flutter waves (Fig. 3). Such rhythms have been thought to be unresponsive to rapid atrial pacing.[14,17] In spite of the electrocardiographic appearance of atrial fibrillation in this patient and the documented presence of local atrial fibrillation at some sites in the right atrium, the predominant rhythm was atrial flutter which could be terminated by rapid atrial pacing. It may be that other patients with so-called flutter-fibrillation or impure flutter who were previously assumed to require pharmacologic intervention or DC cardioversion may, instead, be effectively treated with rapid atrial pacing, thus sparing them the risks inherent in these other therapies. One should not discard rapid atrial pacing as ineffective in any given patient unless multiple pacing rates and multiple pacing sites have been thoroughly explored.

Echocardiographic Features of Carcinoid Heart Disease

JOHN A. CALLAHAN, MD, EDMUND M. WROBLEWSKI, MD, GUY S. REEDER, MD, WILLIAM D. EDWARDS, MD, JAMES B. SEWARD, MD, and ABDUL J. TAJIK, MD

We reviewed the records of the Mayo Clinic patients with known carcinoid syndrome in whom echocardiographic studies had been done. Nineteen patients had M-mode and 2-dimensional echocardiographic examinations, and 1 patient had an M-mode examination only. Of the 20 patients, 8 had no evidence by echocardiogram of carcinoid heart disease; 2 had changes in the tricuspid valve echogram suggestive of early carcinoid heart disease, and the other 10 patients had the following distinctive echocardiographic findings: (1) the pattern of right ventricular volume overload (enlarged right ventricle with abnormal septal motion); (2) abnormal right-sided valves, including (a) a striking appearance of the tricuspid valve, the leaflets appearing thickened, retracted, and fixed in a semiopen position throughout the cardiac cycle, and (b) thickened, retracted pulmonic valve cusps, when visualized; and (3) the left-sided valves and chambers rarely involved. These echocardiographic features are distinctive of advanced carcinoid heart disease and correlate closely with pathologic findings.

Nearly 50 years ago, a distinct form of heart disease was described in patients with carcinoid syndrome.[1–3] It has since been recognized that cardiac involvement occurs as a late complication in approximately half of patients with carcinoid syndrome.[4,5] In many, the predominant terminal symptoms and death may be attributed directly to cardiac involvement.[4,6,7] Cardiac pathologic findings in carcinoid heart disease are characterized by peculiar endocardial lesions[4,8] that are specific for the disease and that may lead to significant hemodynamic derangements. They most often involve the pulmonic and tricuspid valves.

The clinical, electrocardiographic, radiologic, hemodynamic, and pathologic features of carcinoid heart disease have been well described.[4,5,7–12] A case report describing echocardiographic features of carcinoid heart disease was recently published.[13] This report describes distinctive echocardiographic features of carcinoid heart disease and correlates these findings with clinical and pathologic features of this disease.

Methods

Patients: The study group of 20 patients included all patients with carcinoid syndrome evaluated at the Mayo Clinic between 1977 and April 1982 for whom echocardiographic data of good quality were available (combined M-mode and 2-dimensional (2-D) examinations in 19 patients with M-mode only in 1 patient). All 20 patients had a diagnosis of malignant carcinoid disease proved by biopsy and were sent for echocardiographic examination. Five were sent for baseline examinations, and the M-mode and 2-dimensional examinations were normal. Fifteen patients were believed to have some evidence of carcinoid heart disease after clinical evaluation. Ten had the distinctive echocardiographic findings of carcinoid heart disease (Group I). The remaining 5 had either normal echocardiograms or evidence of some other heart disease (mitral valve prolapse, ischemic heart disease). These 5 patients and the 5 sent for baseline examinations constituted the other study group (Group II).

M-mode echocardiography: M-mode echocardiograms were obtained with a commercially available ultrasonoscope (Smith Kline Instruments, Ekoline 20A, or Irex System II) and were recorded with a multichannel strip-chart recorder (Cambridge, Honeywell 1856, or Irex). Studies were performed with a 2.25 MHz transducer with a repetition rate of 1,000 Hz.

The end-diastolic measurements for cavity size were taken at the peak of the R wave of the electrocardiogram. Systolic measurements of left ventricular internal dimensions were done at the peak of posterior wall motion. An estimate of global left ventricular function was determined by fractional shortening: $[(D_d - D_s)/D_d] \times 100$, where D_d and D_s are left ventricular dimensions at end-diastole and end-systole, respectively.

2-D echocardiography: 2-D echocardiographic examinations were performed with a commercially available wide-angle, phased-array sector scanner (Varian Associates, model V-3000 or V-3400). The transducers, with a frequency of 2.25 MHz, had 32 piezoelectric crystals in linear array. Images were recorded directly on a ¾ inch videocassette recorder (Sony VO-2800). Patients were examined supine or in a left semilateral decubitus position. The cross-sectional views of the heart were obtained from the parasternal, apical, and subcostal positions.[14] By qualitative analysis, left ventricular size and function, right atrial, right ventricular, and left atrial size, ventricular septal motion, and valvular structure were designated normal or abnormal. Abnormalities were graded as mild, moderate, or severe.

Results

Clinical Findings

Group I, 10 patients (Table I): There were 7 women and 3 men, aged 20 to 72 years (mean 52). The site of origin of the primary carcinoid lesion, determined in 4 patients, was the colon in 2 and the ileum in 2. Hepatic metastases were present in 9 patients. Peak quantities of 5-hydroxyindoleacetic acid in 24 hour urine samples were abnormally high in 3 patients. They were normal in 1 patient, who had abnormally high serum levels of serotonin. In 1 patient the determination was not made. On the basis of cardiovascular examination, tricuspid valve disease with regurgitation or combined stenosis and regurgitation was suspected in all 10 patients. Jugular venous pressure was elevated in all 10 patients. Diastolic decrescendo murmur, probably representing aortic valve regurgitation, was noted in 1 patient. Nine patients were in New York Heart Association[15] class III or IV at the time of the echocardiographic examination, and 1 patient was in class I.

The electrocardiograms of all 10 patients showed sinus rhythm. One patient had first degree atrioventricular block, and 1 patient had complete right bundle branch block and prolonged Q-T interval. Other electrocardiographic abnormalities were atrial conduction delay (1 patient), right-axis deviation (1), right atrial enlargement (1), right ventricular hypertrophy (1), nonspecific S-T and T-wave abnormalities (4), and low anterior forces (1).

Chest roentgenograms were normal in 3 patients, cardiomegaly was present in 5, and pleural effusion was present in 4.

Six patients died between the time of the echocardiographic examination and completion of this study. Four patients were still living at the time of this study, 7 months to 10 years after the clinical diagnosis of carcinoid syndrome had been made.

Group II, 10 patients (Table I): Seven female and 3 male patients were included. The ages ranged from 40 to 76 years (mean 60). The site of origin of the primary lesion, determined in 8 of the 10 patients, was the ileum in 7 and the colon in 1. Hepatic metastases were present in all 10 patients. Urinary levels of 5-hydroxyindoleacetic acid were elevated in 9 patients and normal in 1. In 3 patients no murmurs were noted. Basal flow murmurs were noted in 2 patients, an apical systolic murmur and mid-systolic click suggestive of mitral regurgitation were noted in 1 patient, a grade 3 systolic murmur suggestive of tricuspid insufficiency was noted in 1, and murmurs suggestive of combined mitral and aortic regurgitation were noted in 1. Jugular venous pressure was elevated in 4 patients and normal in the other 4.

The electrocardiograms of all 10 patients showed sinus rhythm. In 5 patients the findings were normal. Two patients had nonspecific ST-T wave abnormalities. One patient had first degree atrioventricular block and complete left bundle branch block, and 1 had sinus tachycardia and right-axis deviation.

Chest roentgenographic findings were normal in 8 patients; 1 patient had pulmonary congestion and 1 had a pleural effusion, but heart size was normal in both.

Three patients died between the time of echocardiographic examination and completion of this study. Seven patients were still alive at the time of this study,

1 month to 5.5 years after the clinical diagnosis of carcinoid syndrome had been made.

Echocardiographic Findings

Group I, M-mode echocardiographic findings (Table II): All 10 of the patients with carcinoid heart disease had the features of right ventricular volume overload (enlarged right ventricle and abnormal motion of the ventricular septum). In 6 of the 10 patients, the tricuspid valve was greatly thickened and had either greatly diminished excursion or an undulating motion during the cardiac cycle. The tricuspid valve echo could not be recorded in 3 patients. Diastolic fluttering of the anterior leaflet of the tricuspid valve was noted in 1 patient. The pulmonic valve echogram was not recorded in any of the 10 patients.

The left ventricular wall thickness, left ventricular cavity, and left atrial size were normal in all patients. The mitral valve appeared normal in 9 patients. (The patient with aortic regurgitation and 1 additional patient had diastolic fluttering of the anterior mitral valve leaflet.) One patient (1) had mitral valve prolapse. Small (posterior) pericardial effusions were present in 3 patients.

2-D echocardiographic findings (Table III): Of the 9 patients with carcinoid heart disease who had 2-D echocardiographic examination, all had right ventricular volume overload (Fig. 1), which confirmed the M-mode findings. The most striking abnormalities were found when the tricuspid valve was examined. The leaflets, specifically anterior and septal, were thickened and retracted and had greatly diminished mobility (4 had essentially no mobility, and 3 had slight motion at the extreme tip of the anterior tricuspid leaflet) (Fig. 2). There was incomplete coaptation of the anterior and the septal leaflets. The leaflets appeared fixed in a semiopen position, so that the orifice remained open throughout the cardiac cycle (Fig. 3 and 4). In 1 patient with severe heart disease, mobility was retained in the anterior tricuspid leaflet, but the septal leaflet was rigid and normal coaptation failed. In 2 patients, adequate visualization of the subvalvular structures demonstrated

TABLE III Two-Dimensional Echocardiographic Findings in Patients With Carcinoid Heart Disease*

Case	Mitral Valve	Aortic Valve Cusps	Tricuspid Leaflets	Pulmonic Cusps	PE	AS

8	Normal	Normal	Septal thickened	Not seen	+	Bulges right
9	Normal	Normal	Thickened, retracted, fixed	Thickened; retracted	0	Normal
10	Normal	Normal	Septal thickened, immobile	Retracted	0	Normal

* A 2-D examination was not done in Patient 7.
AS = atrial septum; LA = left atrium; PE = pericardial effusion; ↓ = diminished; 0 = none; + = small.

thickening and shortening of the chordae tendineae and papillary muscles. The pulmonary valve cusps, recorded in only 4 patients, were also shortened, thickened, and immobile. These difficulties were encountered in spite of diligent efforts to develop the pulmonary valve echogram and good visualization of right ventricular outflow. The findings were clearly recognized as abnormal by all observers.

The structure and motion pattern of the mitral valve appeared normal in 7 of the 9 patients. The patient in whom mitral valve prolapse was demonstrated by M-mode echocardiogram had prolapse of the posterior leaflet by 2-D examination. The size and function of the left ventricle appeared normal in all patients.

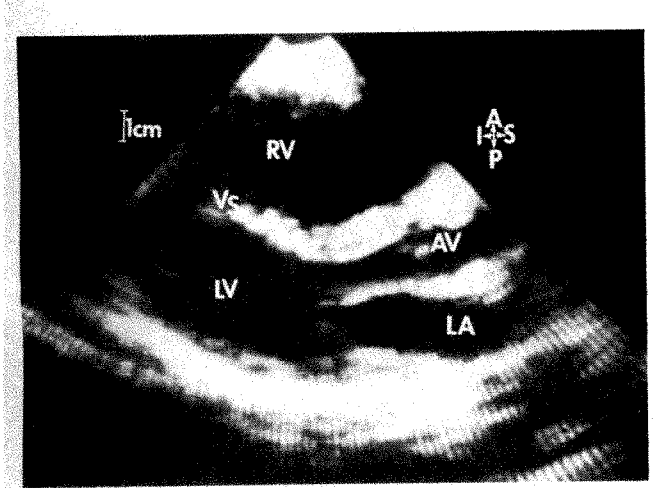

FIGURE 1. Patient 5. Long-axis view of the left ventricle (diastolic frame) shows a normal left ventricle (LV) and left atrial (LA) size, and normal mitral and aortic (AV) valves. The right ventricle (RV) is moderately dilated, and the basal ventricular septum (VS) has an abnormal bulge toward the left ventricle during diastole (abnormal septal motion). A = anterior; I = inferior; P = posterior; S = superior.

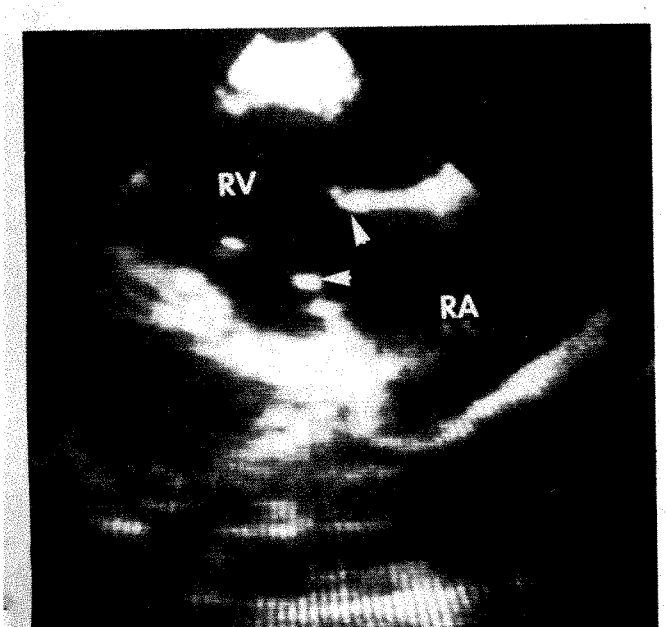

FIGURE 2. Patient 5. Long-axis view of right ventricular inflow shows an enlarged right ventricle (RV) and right atrium (RA). Thickened and retracted anterior and septal leaflets (**arrows**) of the tricuspid valve exhibited little motion during real-time examination and resulted in a fixed orifice.

Group II, M-mode echocardiographic findings: The M-mode echocardiograms were normal in 8 of the 10 patients without demonstrated carcinoid heart disease. One patient had thickening and diminished excursion of the anterior tricuspid valve leaflet but no evidence of right ventricular volume overload. When the M-mode echocardiograms were reexamined, 2 patients (Table II) had changes in the tricuspid valve echogram suggestive of early carcinoid heart disease. One patient had a hyperdynamic heart.

One patient (17) was reexamined 3 years after the initial, normal echocardiogram (Table II). At the time of the second examination (1982), the right ventricle was enlarged and septal motion was abnormal. The septal leaflet of the tricuspid valve was thickened, and mobility was reduced. The anterior tricuspid leaflet appeared normal. The pulmonary valve appeared thickened. The left-sided valves and chambers were normal.

2-D echocardiographic findings: Of the patients in Group II, 8 had essentially normal 2-D echocardiograms. There were instances of calcification in the mitral anulus and slight thickening of the mitral or aortic valve leaflets, findings not unusual in patients of this age. One patient had hyperdynamic cardiac activity but no structural changes in the valves or chambers. One patient had a pericardial effusion.

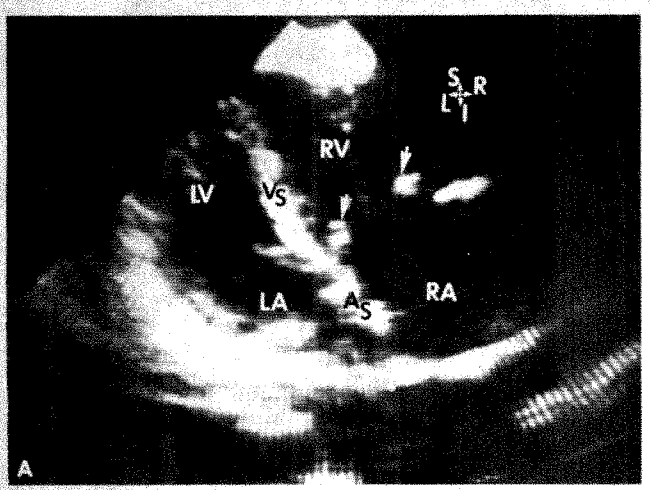
Discussion

Patients with malignant carcinoid tumors may live for many years after the first signs of this disease appear.[6] Some workers[16,17] have suggested that in patients with the slowly progressive form of the disease, cardiovascular lesions are more likely to develop because of the time involved. Cardiac involvement can cause severe and disabling symptoms when right ventricular failure supervenes. In many cases, the predominant terminal symptoms and death may be attributed to intractable right ventricular failure secondary to tricuspid and pulmonary valvular lesions.[18] Experience with successful surgical treatment of the valvular lesions in carcinoid heart disease is increasing, and a more aggressive surgical approach to the treatment of the cardiovascular complications of this disease has been proposed.[16–23] Therefore, accurate diagnosis and adequate treatment of the cardiac manifestations are imperative in the long-term management of patients with malignant carcinoid.

Definitive diagnosis of carcinoid heart disease may be difficult. Specific roentgenographic findings do not exist, although the right atrium or right ventricle may be enlarged.[4] Likewise, the electrocardiogram is of little specific help in diagnosis. Right bundle branch block, right-axis deviation, low QRS voltage, and prominent P waves suggesting right atrial enlargement have been noted in patients with carcinoid heart disease.[6] Similarly, the urinary levels of 5-hydroxyindoleacetic acid do not reflect the presence or absence of cardiac in-

volvement.[4] In addition, although the diagnosis of carcinoid heart disease usually is readily suspected by physical examination, some of the physical findings frequently encountered in the carcinoid syndrome—such as cyanosis, hepatomegaly, peripheral edema, ascites, and dyspnea—are not diagnostic of valvular disease in these patients. These signs may result from portal hypertension caused by hepatic obstruction from metastases.

The pathologic findings of carcinoid heart disease are distinctive.[4,9] Carcinoid plaques in the heart, histologically pathognomonic, represent mounds of endocardial (or intimal) smooth muscle proliferation. Although any cardiac chamber or great vessel may be involved, the



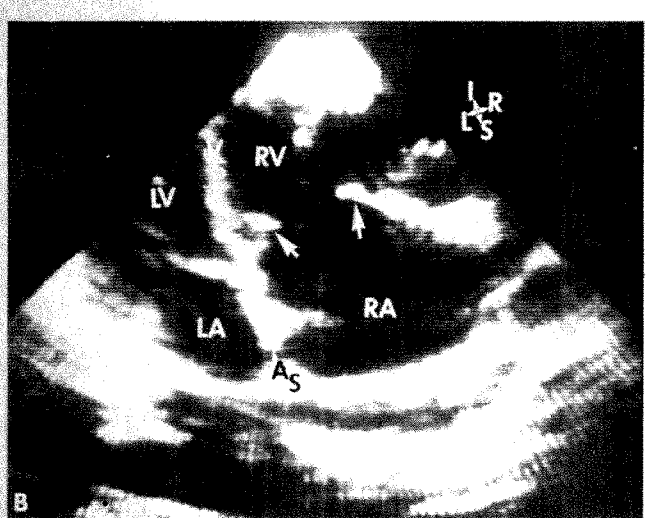


FIGURE 3. Patient 5. Four chamber view shows an enlarged right ventricle (RV) and right atrium (RA): **A,** diastolic frame; **B,** systolic frame. Note the typical appearance of the tricuspid valve as described in Figure 2 legend. Orifice is fixed in semiopen position and measures 2 cm across. AS = atrial septum; I = inferior; L = left; LA = left atrium; LV = left ventricle; R = right; S = superior; VS = ventricular septum.

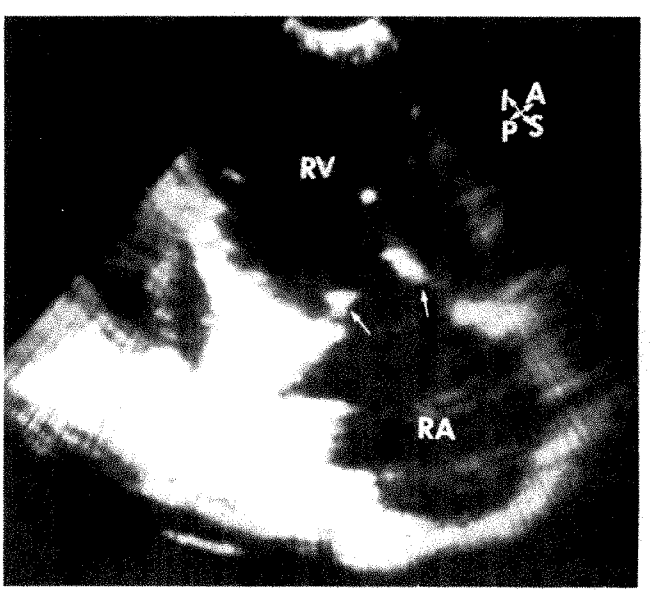

FIGURE 4. Patient 2. Right ventricular inflow view from the parasternal position shows an enlarged right atrium (RA) and right ventricle (RV). Note the thickened and retracted anterior and septal leaflets (**arrows**) of the tricuspid valve. This valve showed little movement during real-time examination (fixed orifice). A = anterior; I = inferior; P = posterior; S = superior.

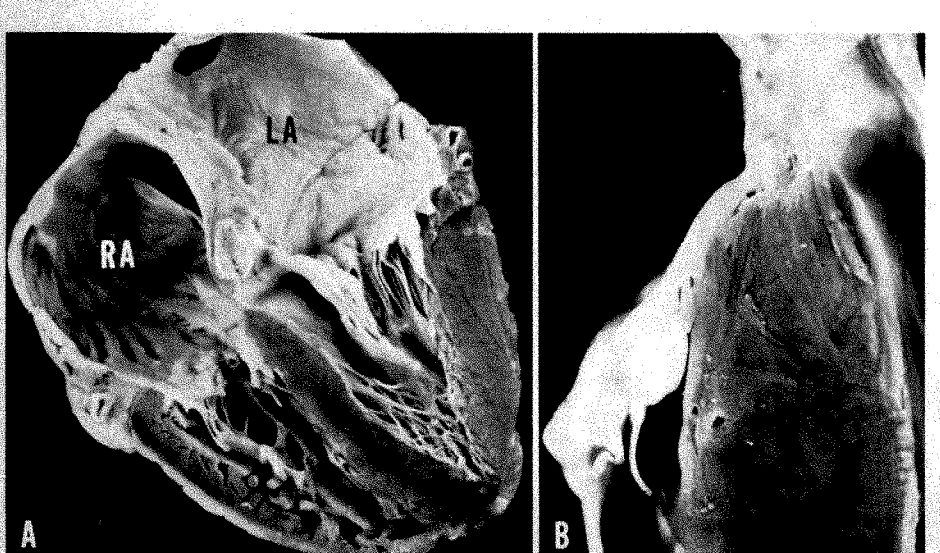

FIGURE 5. A, apical 4 chamber view of a cardiac specimen shows a normal left atrium (LA), mitral valve, and left ventricle and a dilated right atrium (RA), thickened tricuspid leaflets, and hypertrophied right ventricle. **B,** septal tricuspid leaflet thickened by carcinoid plaques and fused to underlying ventricular septum.

tricuspid and pulmonary valves are almost always the most severely involved.[4,8] All valvular components may be involved (anulus, leaflets, commissures, chordae tendineae, and papillary muscles). (Postmortem data in this series were not available for patients who died away from the medical center.)

In the tricuspid valve, circumferential anular involvement is common, and the resulting retraction produces a somewhat stenotic orifice of fixed size (Fig. 5). Plaques may obliterate the valvular commissures. Although such plaques may occur on the atrial or ventricular surfaces of the leaflets, ventricular involvement is more common (particularly of the septal and posterior leaflets), and adherence to the underlying endocardium may rigidly fix the thickened leaflets in semiopened position and result in significant regurgitation.[4] Plaques may also cause thickening and fusion of chordae tendineae and focal thickening of papillary muscles (Fig. 6 and 7).

Anular constriction of the pulmonary valve generally is pronounced and can result in hemodynamically significant stenosis.[4] The cusps are thickened and rigid but tend to be contracted and greatly reduced in size; thus, they contribute to valvular incompetence. Commissures may also be obliterated by plaques (Fig. 8).

This same 2-D appearance of the tricuspid valve in our patients with carcinoid heart disease was distinctive. The tricuspid valve leaflets were thickened and retracted, exhibiting diminished mobility and incomplete coaptation of anterior and septal leaflets. The leaflets remained in a semiopen position throughout the cardiac cycle.

The echocardiographic findings in 2 patients (14 and 15) are of interest. The right atrium and right ventricle

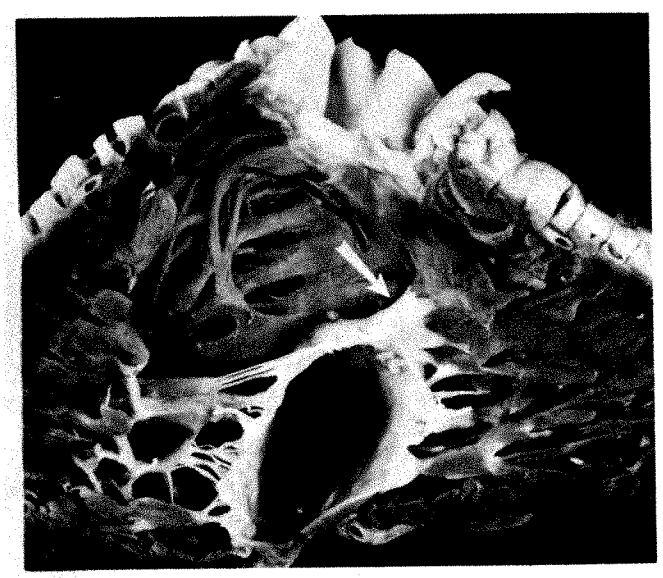

FIGURE 6. Opened right ventricle shows thickened leaflets, thickened and focally shortened and fused chordae tendineae, and extension of carcinoid plaque from the medial papillary muscle onto the inferior limb of the trabecula septomarginalis (**arrow**). The pulmonary valve is also thickened and retracted.

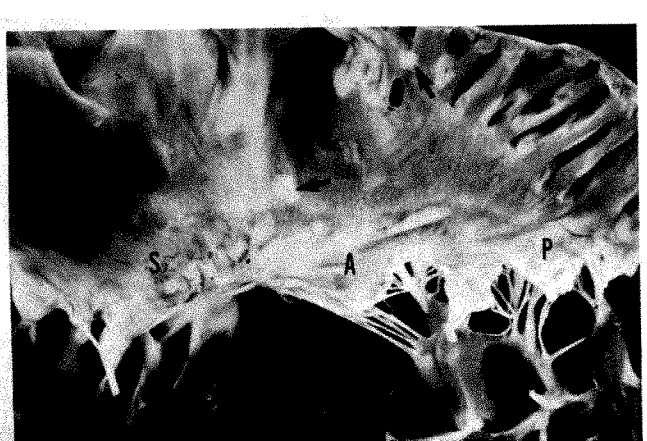

FIGURE 7. Opened tricuspid valve with thickened leaflets, vascularization of the anterior leaflet (A), obliteration of the commissure between the anterior and septal (S) leaflets, focal thickening of the chordae tendineae to the anterior and posterior (P) leaflets, encasement of the septal chordae tendineae by carcinoid plaques, and extension of the plaques onto the papillary muscles and right ventricular myocardium. Note the numerous right atrial endocardial carcinoid plaque (**arrows**).

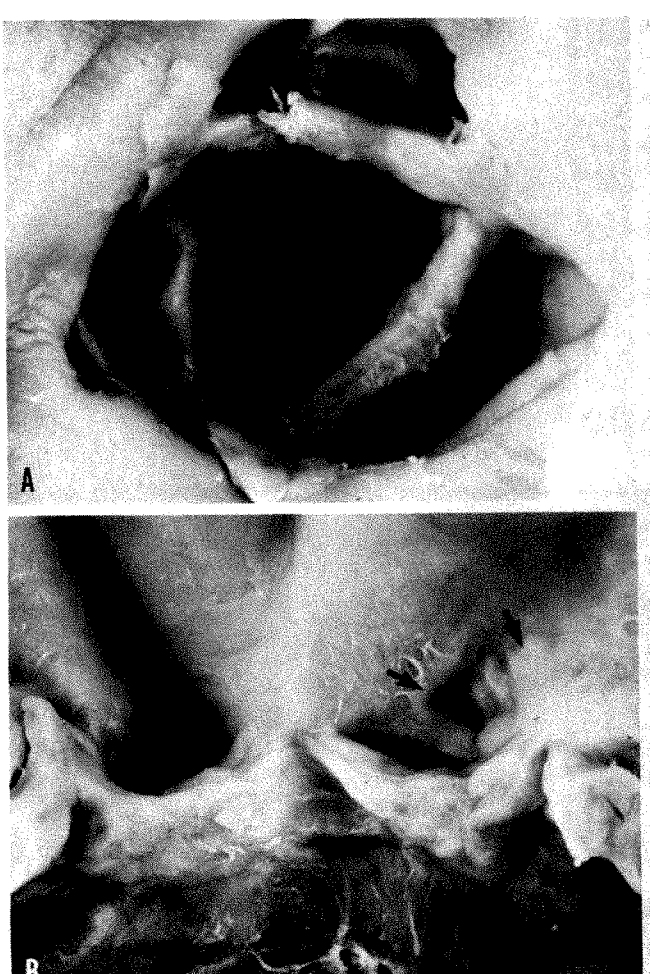

FIGURE 8. Pulmonary valve viewed from above (**A**) and opened (**B**). The thickened and retracted cusps result in valvular incompetence. The constricted anulus results in valvular stenosis. Carcinoid plaques (**arrows**) extend onto the pulmonary trunk.

were normal. In both patients, the anterior tricuspid leaflet was thickened but the excursion of the valve was normal. Although these findings are not specific, in patients who have malignant carcinoid syndrome they may represent early thickening of the tricuspid valve leaflets from carcinoid heart disease that has not yet caused demonstrable functional abnormalities. Unfortunately, postmortem examination was not done in either patient. Patient 17 was reexamined 3 years after a normal examination and was found to have thickening and loss of mobility of the septal leaflet of the tricuspid valve accompanied by early volume overload of the right ventricle. This case suggests that serial examinations may be important to demonstrate abnormalities more surely.

Our inability to image the pulmonary valve despite clear views of the right ventricular outflow tract and main pulmonary artery suggests that the pathologic process resulting in pulmonary valve contraction (greatly reduced cusp size) inhibited image formation (Fig. 8B). In patients with normal mitral and aortic valves, the findings of thickened, fixed, and retracted tricuspid valve leaflets and pulmonary cusp or cusps associated with an enlarged right ventricle and right atrium are virtually diagnostic of advanced carcinoid heart disease.

In the differential clinical diagnosis of tricuspid valvular disorders that may be associated with significant regurgitation, one must consider not only carcinoid heart disease but also rheumatic valvular disease, tricuspid valve prolapse, ruptured chordae tendineae, eosinophilic endomyocardial disease, endocardial fibroelastosis, Ebstein's anomaly, and congenital tricuspid dysplasia (dysgenesis). The echocardiographic features of these entities are specific and should allow differentiation. Rheumatic tricuspid valve involvement occurs almost always with rheumatic involvement of the left-sided valves, while the pulmonic valve is intrinsically normal and is usually readily visualized. Although left-sided valvular involvement by carcinoid heart disease has been reported,[10,12] the involvement of tricuspid and pulmonic valves just described is distinctive and should allow the correct diagnosis. The rheumatic tricuspid valve appears thickened and retracted and demonstrates a diastolic doming motion similar to that seen in mitral stenosis. Such doming motion was not seen in any case of carcinoid heart disease. Tricuspid insufficiency secondary to prolapse and ruptured chordae is characterized by increased tricuspid valve excursion associated with prolapse of leaflets into the right atrium. The 2-D features in Ebstein's anomaly are distinctive, consisting of downward displacement of the septal leaflet and elongation of the anterior leaflet. Eosinophilic endomyocardial disease and endocardial fibroelastosis may rarely involve the right side of the heart alone, but the tricuspid valve leaflets, in our limited experience, are normal or mildly thickened and have normal motion, and the pulmonary valve is normal. To date, in our experience, echocardiographic features similar to those in carcinoid tricuspid valve involvement have been seen only in 2 young patients (ages 10 and 14) with congenital tricuspid dysplasia. The pulmonic valve echogram was normal in both. The clinical history and the echocardiographic findings elsewhere in the heart should allow the differentiation of carcinoid heart disease from these other disorders.

In conclusion, the following 2-D echocardiographic findings appear specific for advanced carcinoid heart disease: (1) evidence of right ventricular volume overload; (2) abnormal right-sided valves, including (a) the distinct pattern of thickened, retracted tricuspid leaflets that fail to coapt in systole, and (b) thickened and retracted pulmonary valve cusps; and (3) absence of involvement of the left-sided valves and chambers. In addition, the early stages of tricuspid valve involvement appear to be thickening of the tricuspid leaflets, nearly normal motion, and normal cardiac chamber sizes. Considered in the context of cases with no or early cardiac involvement, these features should serve as a basis for early diagnosis and serial assessment of carcinoid heart disease.

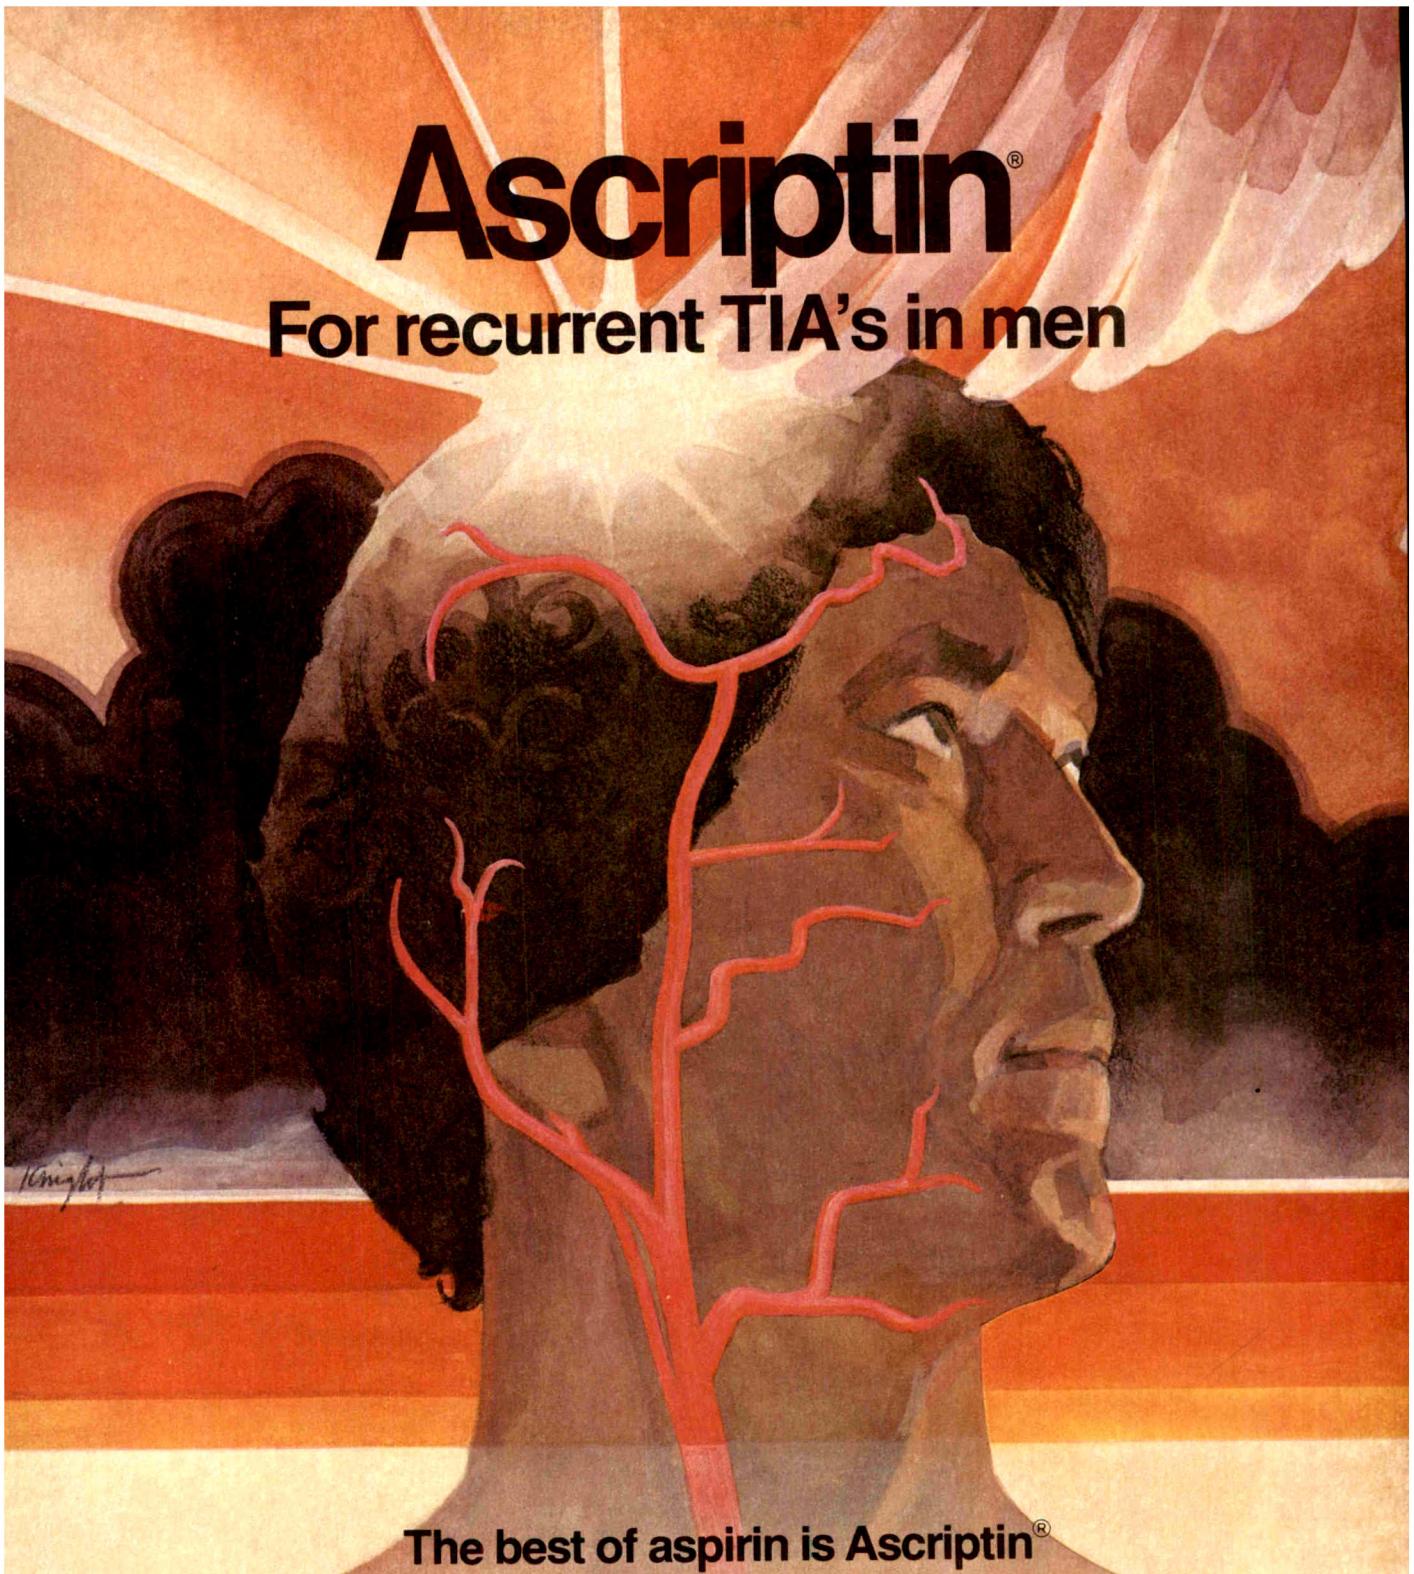
Ascriptin®

For recurrent TIA's in men



The best of aspirin is Ascriptin®

Indications: For reducing the risk of recurrent transient ischemic attacks (TIA's) or stroke in men who have had transient ischemia of the brain due to fibrin platelet emboli. There is inadequate evidence that aspirin or buffered aspirin is effective in reducing TIA's in women at the recommended dosage. There is no evidence that aspirin or buffered aspirin is of benefit in the treatment of completed strokes in men or women.

Precautions: (1) Patients presenting with signs and symptoms of TIA's should have a complete medical and neurologic evaluation. Consideration should be given to other disorders which resemble TIA's. (2) Attention should be given to risk factors: it is important to evaluate and treat, if appropriate, other diseases associated with TIA's and stroke such as hypertension and diabetes. (3) Concurrent administration of absorbable antacids at therapeutic doses may increase the clearance of salicylates in some individuals. The concurrent administration of nonabsorbable antacids may alter the rate of absorption of aspirin, thereby resulting in a decreased acetylsalicylic acid/salicylate ratio in plasma. The clinical significance on TIA's of these decreases in available aspirin is unknown.

Dosage: 1300 mg a day, in divided doses of 650 mg twice a day or 325 mg four times a day.

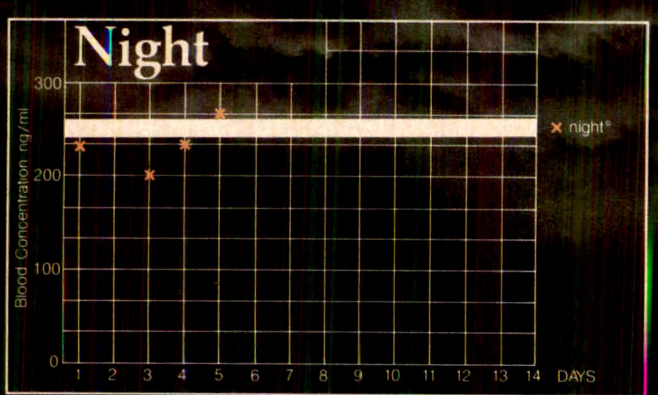
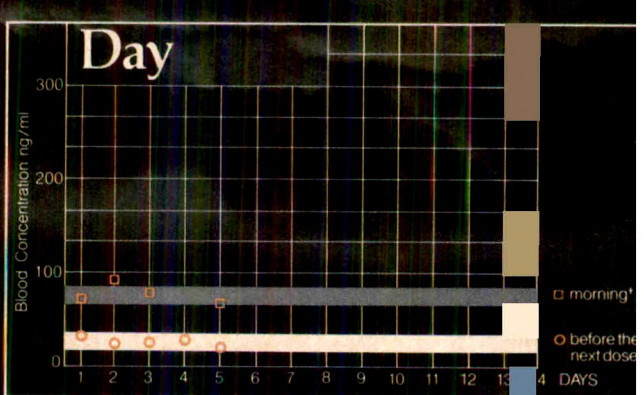
The difference between night...

RESTORIL® (temazepam) blood levels after consecutive nightly 30-mg doses[1,2]





RESTORIL® (temazepam): Effective at night—little residual daytime medication—patients awake alert and refreshed

The half-life of RESTORIL (temazepam) parallels normal sleep time. In contrast, the major active metabolite of flurazepam has a 65-hour mean half-life. With RESTORIL therapy, a major portion of active material is cleared by early morning—enabling patients to awake alert and refreshed.

No significant impairment of daytime activities

In double-blind, placebo-controlled studies,[3,4] no detectable impairment in cognitive function or motor coordination occurred in patients who had taken a 30-mg dose of RESTORIL (temazepam) the night before. In the same studies, poorer performance scores were attained by patients who had taken a 30-mg dose of flurazepam prior to bedtime.

Patients receiving benzodiazepines should be cautioned about possible combined effects with alcohol and other CNS depressan and about operating machinery or driving a vehicle after ingesting the drug.

Sleep time and quality significantly improved

In 21 double-blind studies[5] involving 1,221 adult patients (508 of whom received RESTORIL capsules), RESTORIL therapy provec highly effective from the first night of administration. RESTORIL (temazepam) is indicated for the relief of insomnia associated with the complaints of difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakenings from the first nigh REM sleep remained essentially unchanged. Patients reported a significant improvement in the general quality of sleep.

*night: 3 hours after a nightly 30-mg dose. †morning: 12 hours after a nightly 30-mg dose. ‡before the next dose: 24 hours after a nightly 30-mg dose.

RESTORIL® (temazepam) C-IV capsules
One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*
INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.
The possibility that the insomnia may be related to a condition for which there is more specific treatment, should be considered.
CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.
WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.
PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.
If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.
Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.
Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.
Pregnancy: Pregnancy Category X. See Contraindications.
Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.
ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.
Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.
DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.
SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). SDZ1-159

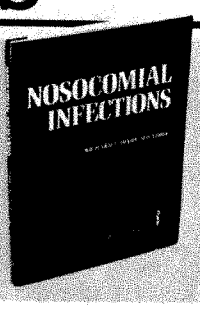
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

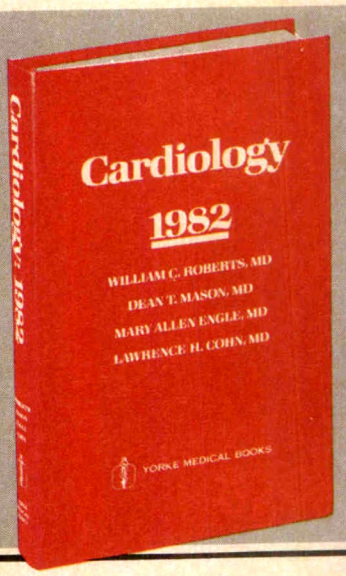
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

Starr-Edwards Silastic Ball Valve

Absolutely a Valve for Today

It's an astonishingly simple concept: The design involves total separation of the occluder mechanism from the orifice. The object is unobstructed blood flow through the orifice.

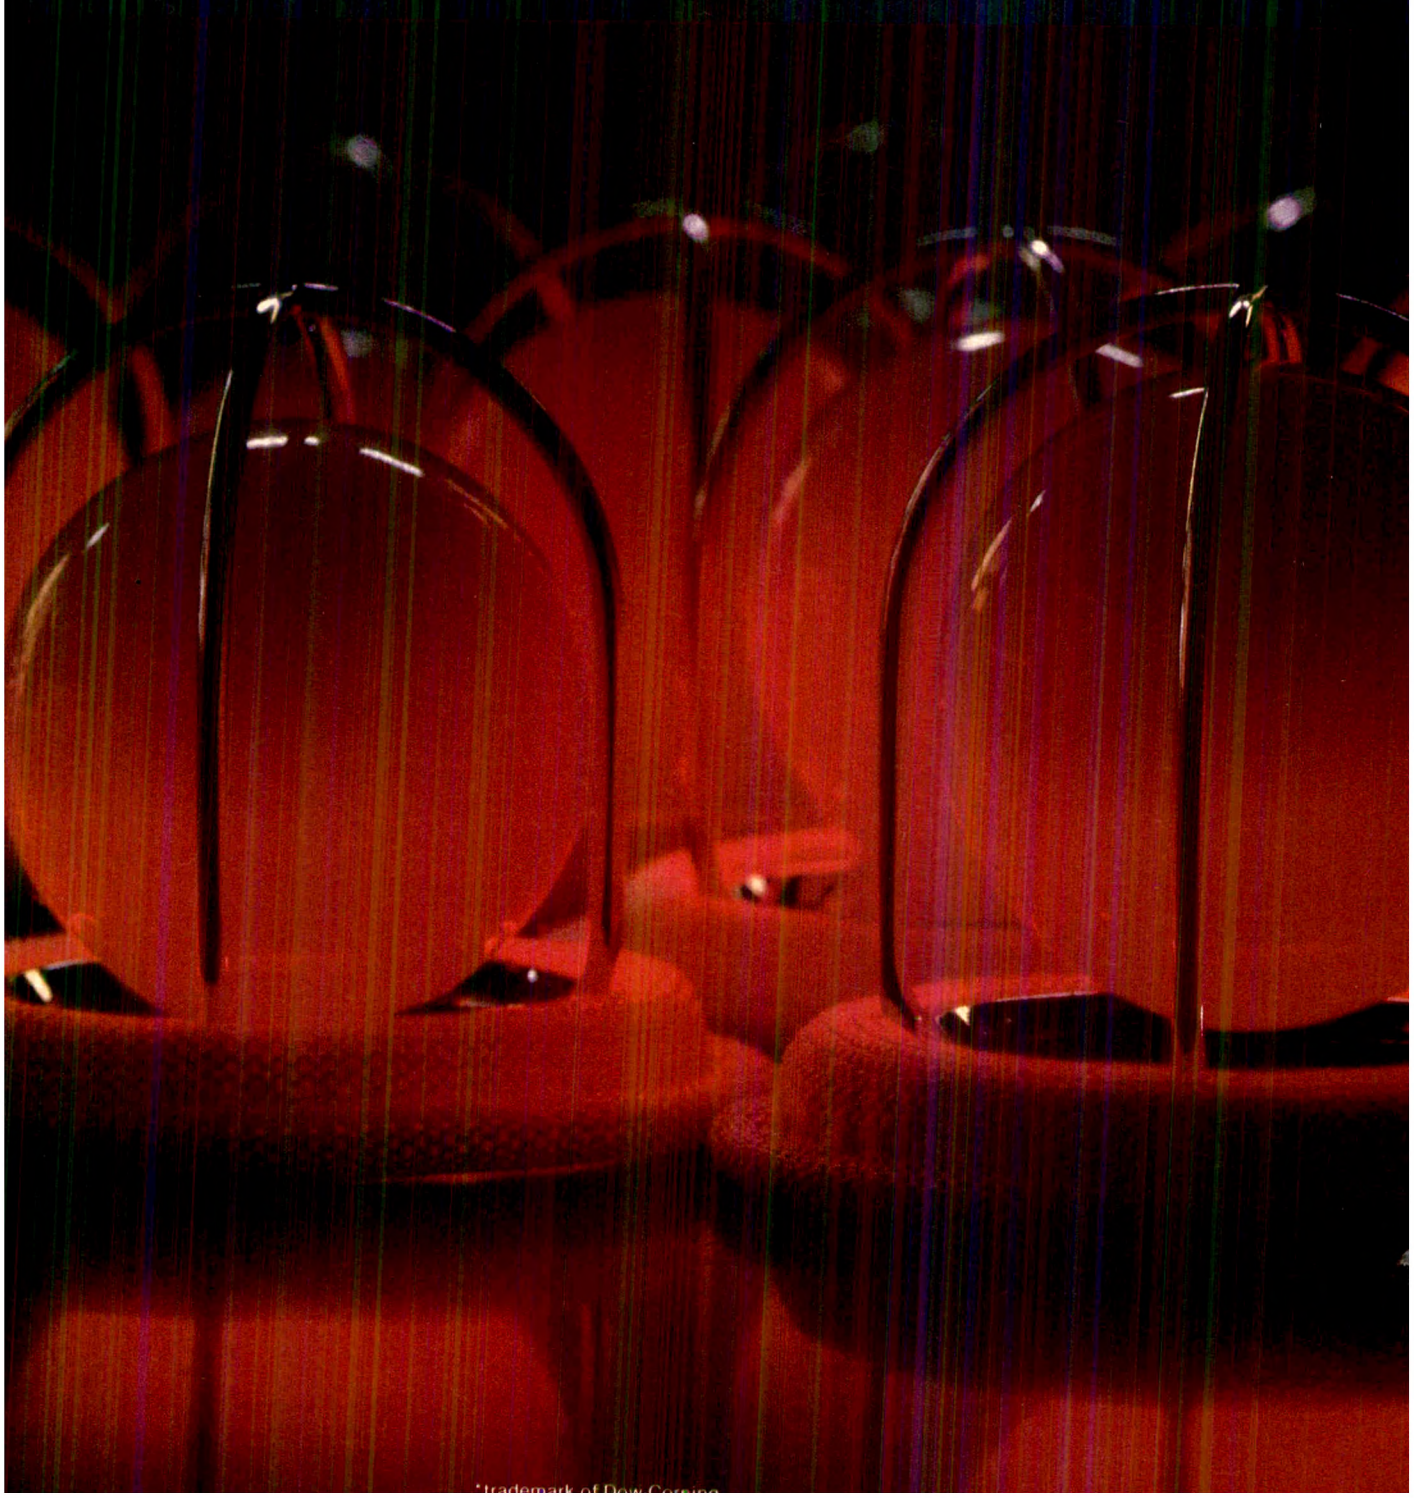
The ball and cage concept made sense twenty years ago when the very first artificial heart valve was introduced, and it has since proven its worth as a viable solution to today's heart valve requirements. After sixteen years of clinical experience with the current Starr-Edwards Silastic Ball Valve, what was once a promising idea is now a proven technology.

An Open and Shut Case

The Starr-Edwards Silastic Ball Valve offers the longest clinical history of any heart valve prosthesis and a record of structural integrity that remains unsurpassed.

One reason is the simple design of the cobalt-chromium cage, cast in one piece, eliminating hinges and joints.

The simple spherical shape of the silastic poppet offers an infinite number of seating surfaces and a clean rinse. Positive and full



*trademark of Dow Corning

osure provides for minimal regurgitation.

Unlike other mechanical prostheses, the tarr-Edwards Silastic Ball Valve is virtually oiseless.

Most importantly, the Silastic Ball Valve as demonstrated a low incidence of catatrophic failure.

imply Predictable

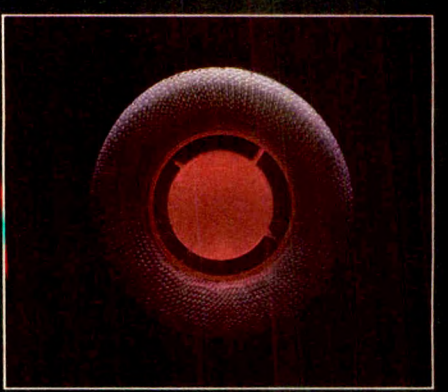
he Starr-Edwards Silastic Ball Valve is asically a simple idea—but one that has een the answer in an estimated 122,000 nplants worldwide.

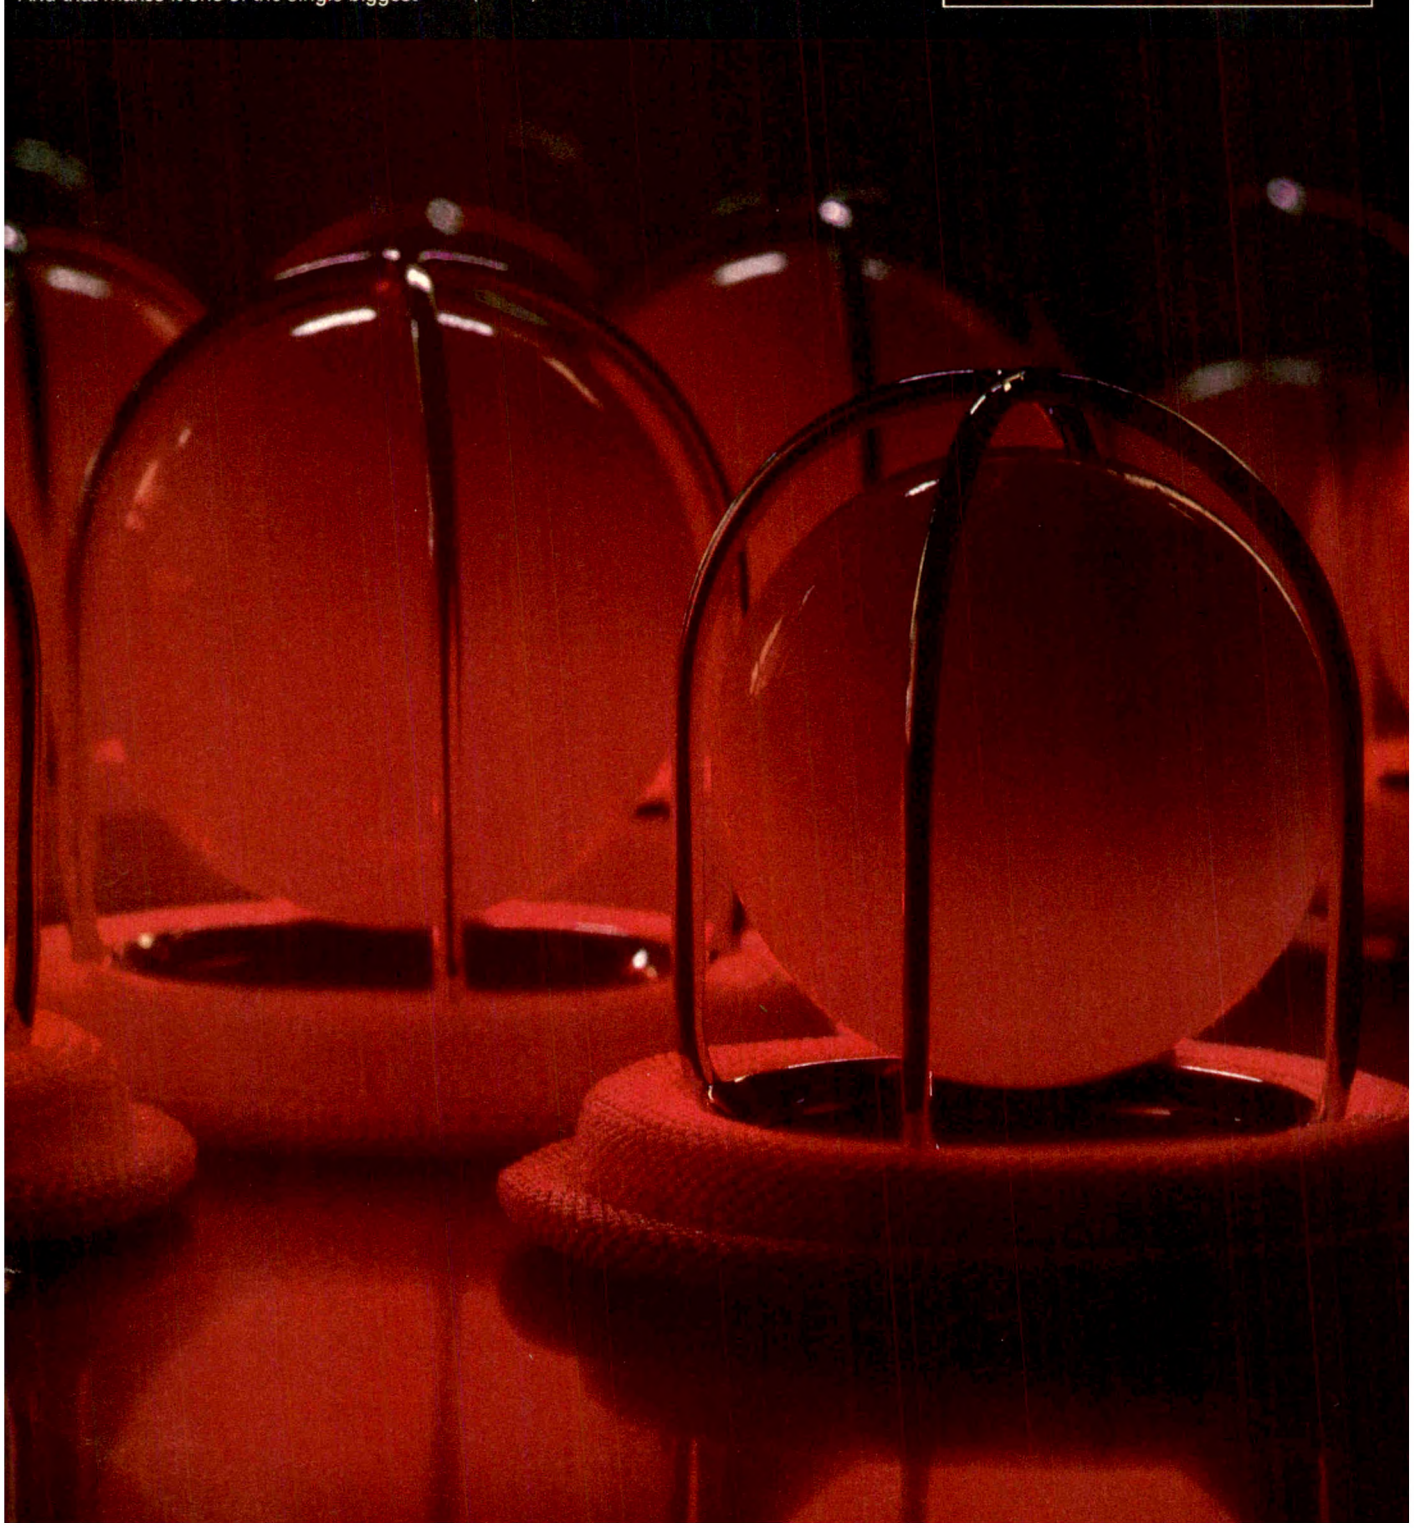
And that makes it one of the single biggest contributors to the growth of heart valve replacement from a rare procedure to an accepted practice.

When it comes to patient quality of life, it's not just promises that count—it's predictability and proven performance.

Refer to product data sheets for current warnings, precautions, and instructions for use.

For further information, please contact American Edwards Laboratories, P.O. Box 11150, 17221 Red Hill Avenue, (Irvine) Santa Ana, CA 92711.





Intracoronary Infusion

American Edwards Takes the Technology Further Than Ever Before

With over a million myocardial infarcts in the U.S. every year and an associated 30 percent mortality rate, researchers have begun concentrating their efforts on drug lysis of intracoronary thrombi as a promising new avenue of patient management.[1,2]

Introducing the Ganz-Edwards™ Coronary Infusion Catheter

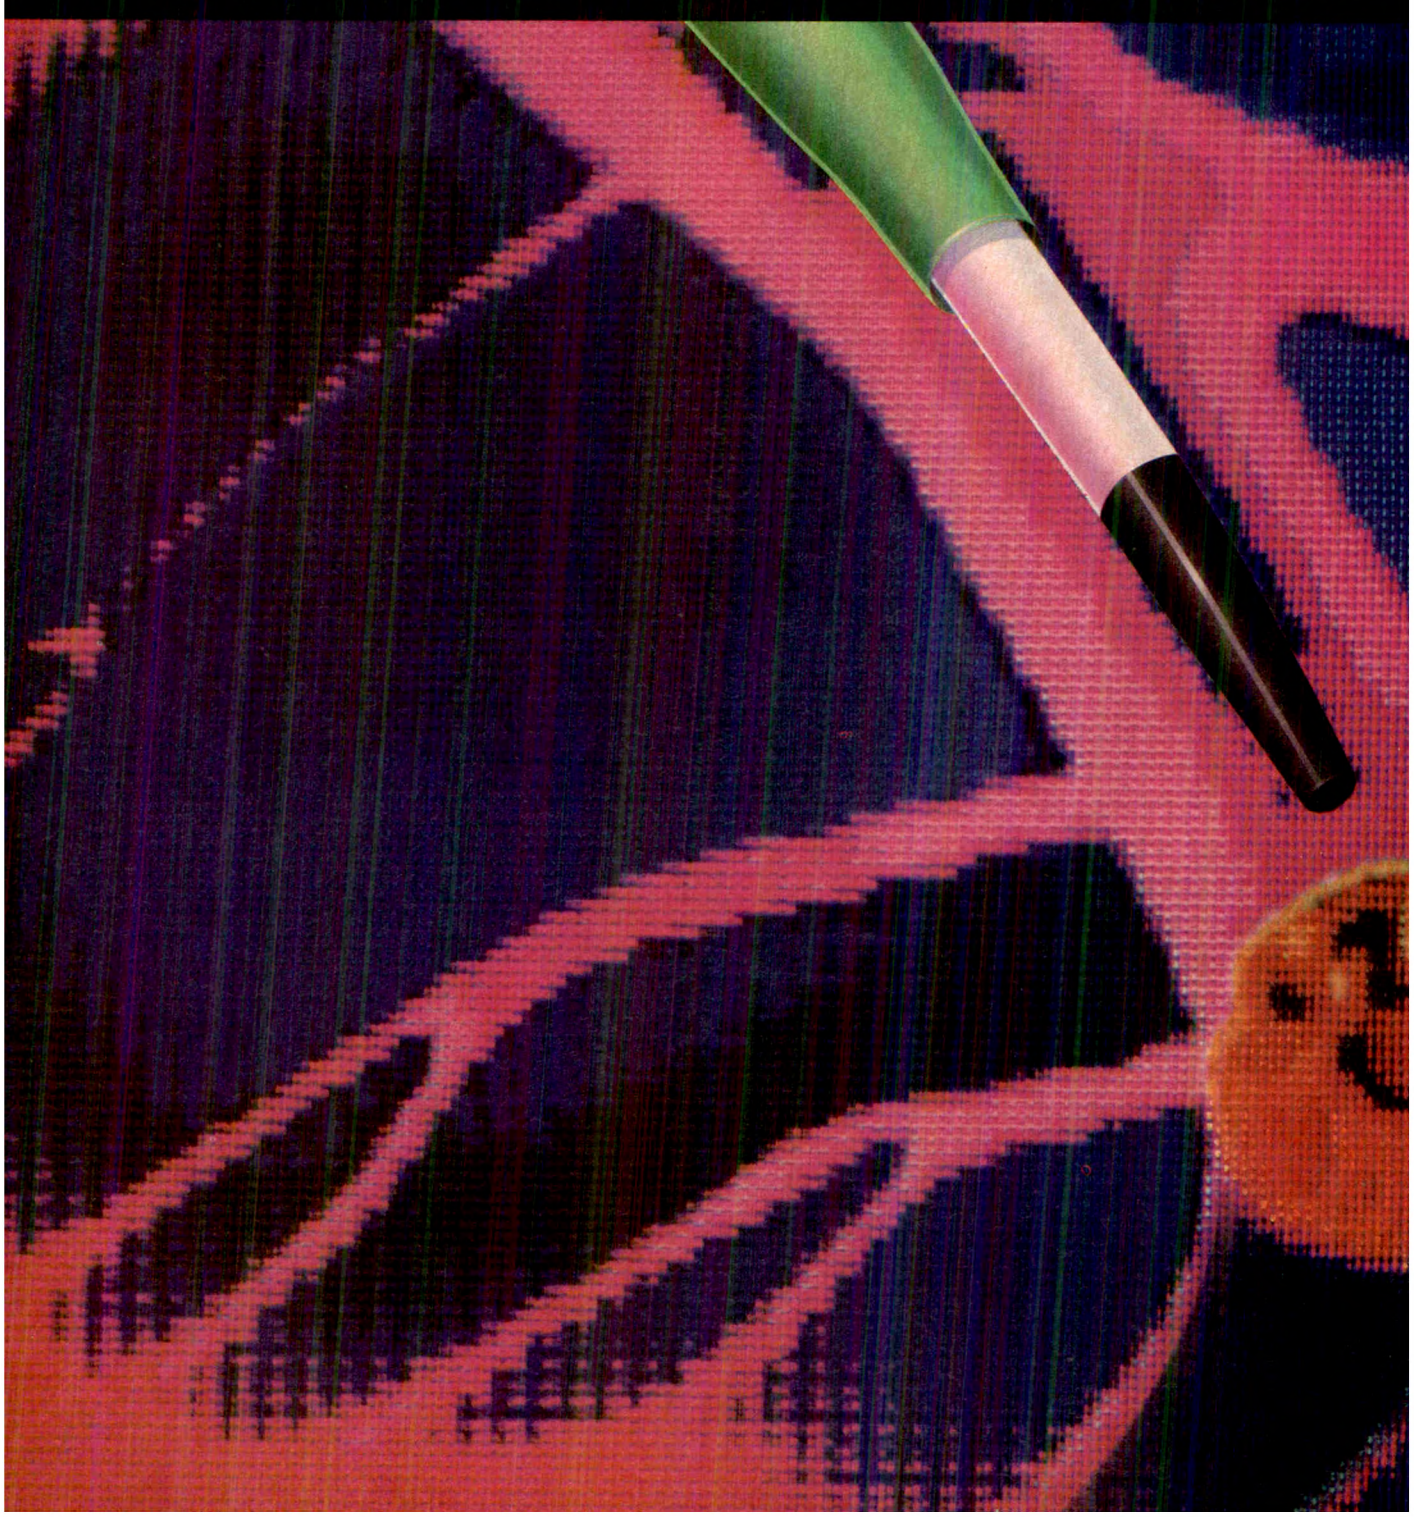
Advancement of the Coronary Infusion Catheter through an angiography catheter, already in place at the ostium, permits drug infusion inside the coronary arteries at the exact site of the clot.

Because delivery is so specific, drug dilution is minimized. Shunting of the thrombolytic agent away from the target area into proximal branches is dramatically reduced.[3]

Concentration of the thrombolytic agent the target area substantially accelerates clot lysis, so critical in myocardial salvage.[3]

Pressure Monitoring Combined with a Radiopaque, Atraumatic Tip

With sub-selective coronary infusion at the forefront of technology, the Ganz-Edwards Coronary Infusion Catheter improves the technique with these added benefits:



] An atraumatic distal 20 cm for safer vancement into distal locations of the ronary vasculature.
] A reduced lumen size for continuous essure monitoring and contrast injection rough the angiography catheter, without usion interruption.
] A radiopaque distal tip with a level of ibility that is unsurpassed.

inging Concept and chnology Together

r over 25 years, American Edwards has en merging promising concepts in critical care medicine, with the technology to make those ideas tangible.

From heart valve replacement, to hemodynamic monitoring, to sub-selective coronary infusion…helping you improve the quality of life is what we're all about.

PROCARDI
(NIFEDIPINE) Capsules 10 mg
PROCARDIA is the beginning of a new age
in the treatment of angina:
The Calcium Age.
It is now known that calcium ions, working at the
cellular level, regulate the degree of vasoconstric
and, thereby, play a critical role in the anginal att
PROCARDIA acts at the cell membrane to select
block calcium access to the contractile process
arterial cell.
Through this action, PROCARDIA mana
—vasospastic angina, by preventing co
nary artery spasm and increasing myocardi
supply
—classical effort-associated angina, b
peripheral arteries to reduce afterload and
myocardial O_2 demand
—mixed angina, which involves eleme
vasospastic and effort-associated angina
Like beta blockers, PROCARDIA reduces myoc
demand. But, unlike these agents, PROCARDI
increases myocardial O_2 supply to both norma
poststenotic areas[1] of the myocardium by pre
coronary artery spasm.

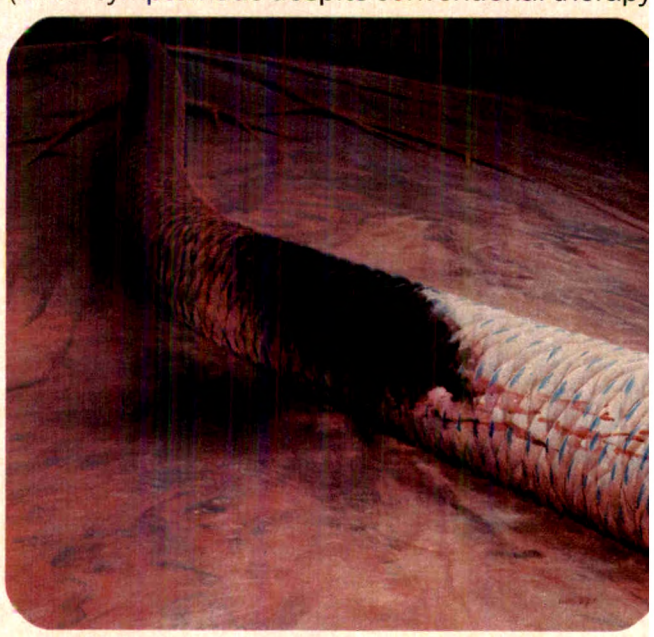
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

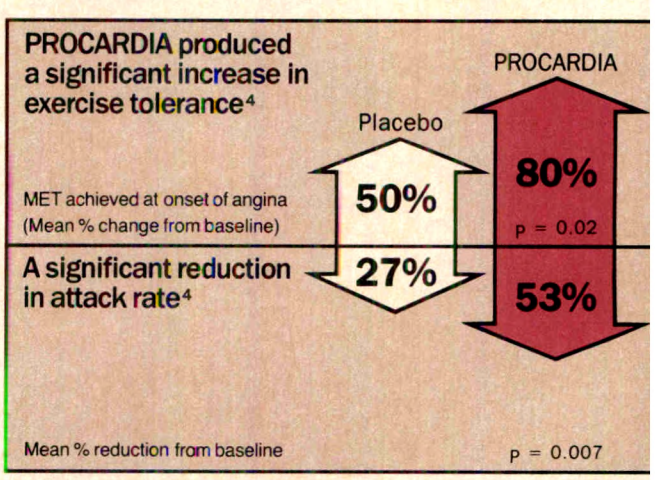
PROVEN EFFECTIVE ACROSS THE SPECTRUM OF ANGINA

Contemporary medical opinion holds that the pathophysiology of angina is a spectrum ranging from pure, fixed atherosclerotic lesion to pure coronary artery spasm. Many patients, however, are believed to have a combination of both lesion and spasm.[2,3]

Angina due to pure fixed lesion can be prevented by reducing oxygen demand. Angina due to coronary artery spasm can be treated by preventing the spasm itself, thereby increasing oxygen supply. With this new understanding of angina, optimal antianginal therapy should provide this dual action: increasing O_2 supply while reducing O_2 demand.

In effort angina*
(when symptomatic despite conventional therapy



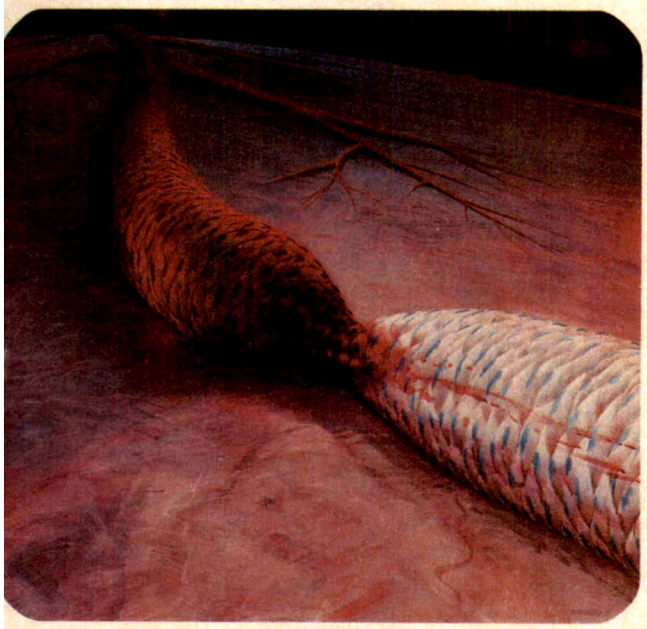


Double-blind, placebo-controlled, crossover 20-week study of 32 patients (27 evaluated for attack rate; 19 for exercis tolerance). Mean PROCARDIA dosage: 51 mg/day.

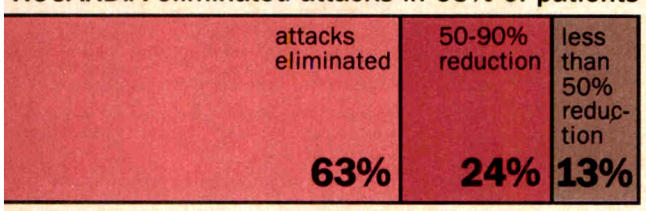
*In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete

Please see PROCARDIA Brief Summary on last page.

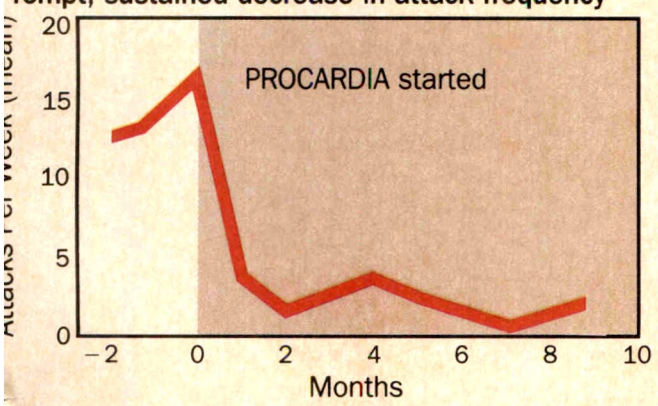
In vasospastic angina



PROCARDIA eliminated attacks in 63% of patients[5]

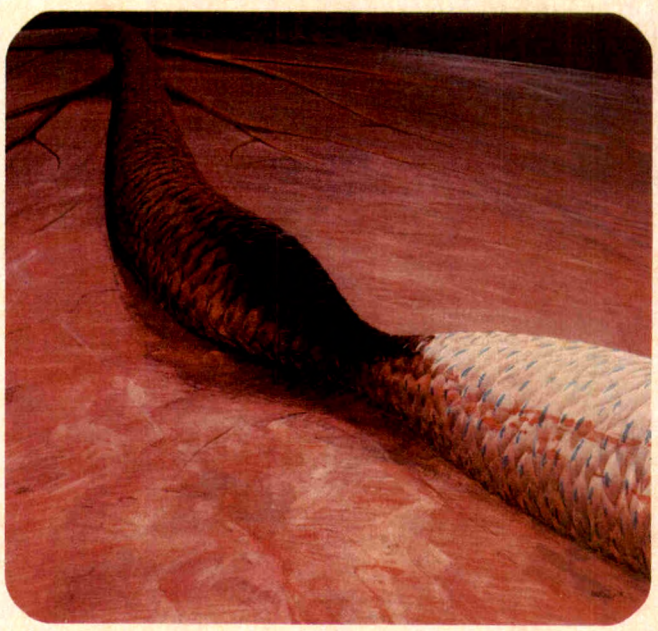


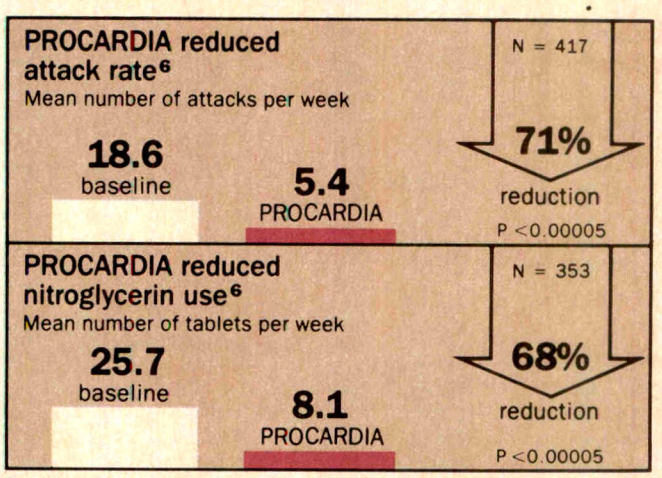
Prompt, sustained decrease in attack frequency[5]



Long-term, open study of 127 patients unresponsive to beta blockers and/or nitrates with symptoms of myocardial ischemia and demonstrated coronary artery spasm. PROCARDIA dosage: 40 to 160 mg/day.

In mixed angina (fixed lesion and spasm)





Studies of patients with mixed angina characterized by pain at rest and effort. Most patients (89%) were initiated on nitrate and/or beta blocker therapy but remained symptomatic. Minimum duration of nifedipine treatment two months. Nifedipine dosage: 30 to 120 mg/day.

PROCARDIA®
THE FIRST ORAL CALCIUM CHANNEL BLOCKER

THE FIRST ORAL CALCIUM CHANNEL BLOCKER FOR THE MANAGEMENT OF ANGINA

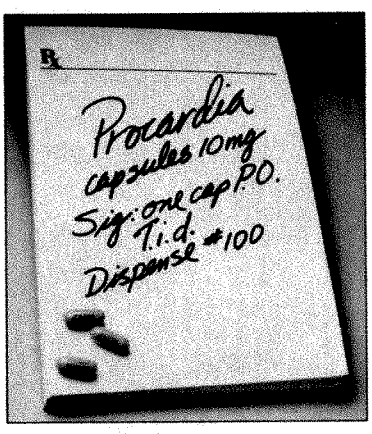
PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

Proven effective when used alone.

Enhanced effectiveness when combined with beta blockers.

Convenient dosing

Start with:	1	10-mg capsule *t.i.d.*
Titrate to:	2	10-mg capsules *t.i.d.*
Titrate to:	3	10-mg capsules *t.i.d.*



For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely. Maximum dose: 180 mg/day

PROCARDIA® CAPSULES For Oral Use

(nifedipine)

BRIEF SUMMARY

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta-blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Increased Angina/Beta Blocker Withdrawal: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients usually receiving a beta blocker have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Pregnancy: Category C.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA Capsule contains 10 mg of nifedipine. PROCARDIA Capsules are supplied in amber glass bottles of 100 capsules (NDC 0069-2600-66).

The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Exercise Electrocardiogram, Blood Pressure, and Working Capacity in Young Patients With Valvular or Discrete Subvalvular Aortic Stenosis

FREDERICK W. JAMES, MD, DAVID C. SCHWARTZ, MD, SAMUEL KAPLAN, MD, and STEVE P. SPILKIN, MD

Electrocardiographic changes, blood pressure, and working capacity (total work) were recorded during an upright cycle exercise test in 65 children and young adults (mean age 12 years) with valvular or discrete subvalvular aortic stenosis. All patients had cardiac catheterization, but none had surgical treatment. Controls consisted of 164 normal subjects (mean age 15 years). In the patients, the intervals between the exercise test and cardiac catheterization were 1 month or less in 66%, 2 to 12 months in 28%, and 12 to 24 months in 6%. The patients were classified by resting left ventricular to aortic peak systolic pressure gradient into Groups I (gradient less than 30 mm Hg), II (30 to 49 mm Hg), III (50 to 69 mm Hg), and IV (70 mm Hg or greater).

The mean frequency and magnitude of exercise-induced S-T depression were greater in the patients than in the control subjects ($p < 0.005$) and increased with increasing obstruction in the patients. Mean total work and peak exercise systolic pressure were significantly decreased in the patients with a left ventricular to aortic systolic gradient of 30 mm Hg or greater as compared with the control subjects ($p < 0.03$). An exercise profile consisting of S-T depression of 2 mm or more, and markedly decreased total work and systolic blood pressure were characteristic of the 19 patients (Group IV) with a resting left ventricular to aortic systolic gradient of 70 mm Hg or greater. At least 2 or more components of this exercise profile occurred in 11 (24%) of the 46 patients with a resting left ventricular to aortic systolic gradient less than 70 mm Hg. This study demonstrates that exercise testing reveals serious abnormalities in patients otherwise classified as having trivial or moderate obstruction, and that a properly performed exercise study can be done at minimal risk to the patient.

During controlled exercise, children with serious left ventricular outflow tract obstruction develop significant S-T depression[1–3] suggesting left ventricular subendocardial ischemia. Several investigators[2,3] reported that significant exercise-induced S-T depression indicates a resting left ventricular to aortic peak systolic gradient of 50 mm Hg or more. Recently, Whitmer et al.[4] reported exercise data in children who were surgically treated for aortic stenosis. In that study, significant S-T depression occurred in patients with a resting left ventricular to aortic systolic gradient of less than 50 mm Hg and resolved after successful surgical relief of obstruction. Preliminary studies[5,6] suggest that exercise blood pressure and working capacity are related to resting left ventricular to aortic peak systolic gradient and are important factors in estimating the severity of aortic stenosis.

Since exercise testing is frequently considered in the evaluation of children with aortic stenosis, this study was designed to determine the electrocardiographic changes, blood pressure, and total work during graded cycle exercise in a cross-section of patients with valvular or discrete subvalvular obstruction of varying severity. These data are analyzed according to resting gradient in order to appreciate the abnormal exercise responses associated with progressive obstruction. This study

should improve our understanding of the disease process, improve the selection of patients for cardiac catheterization or surgery, or both, and assist in providing proper guidelines for conducting exercise tests in children with aortic stenosis.

Methods

Patients: Sixty-five patients (52 male and 13 female) between ages 4 and 24 years (mean 12) with valvular (56) and discrete subvalvular (9) aortic stenosis underwent a cycle exercise test using a continuous graded protocol. Physical examination revealed trivial aortic incompetence in 24 patients and mild to moderate in 8. All patients had cardiac catheterization, and aortography or left ventriculography, or both. There was no exercise intervention during cardiac catheterization.

The exercise test was performed within 1 month of cardiac catheterization in 43 patients. When the exercise study followed catheterization, a minimum of 3 to 4 weeks were permitted to elapse before testing, for maximal relief of leg soreness which may follow insertion of catheters in the groin. In the remaining 22 patients, the exercise study and cardiac catheterization were performed within 2 to 12 months in 18 patients, and 12 to 24 months in 4. During the interim between the exercise study and cardiac catheterization, the clinical examination remained unchanged. For those patients requiring surgical relief of left ventricular outflow tract obstruction, only the data from their preoperative exercise test and cardiac catheterization are included.

Control subjects: One hundred sixty-four children and young adults (100 male and 64 female, aged 5 to 33 [mean 15] years) served as controls. All participants had a normal resting physical examination, supine blood pressure, and resting electrocardiogram. Cardiac arrhythmia was not observed in any subject during a 20 to 30 minute period before the exercise test.

Exercise procedure: The continuous exercise cycle protocol described by James et al.[7] was used. The exercise procedure was explained to the patient and parent or guardian, or both, and informed consent was obtained. The exercise test was conducted by a physician who monitored and instructed the patient during the test, and coordinated the recording of certain variables such as heart rate, blood pressure, and the multiple lead electrocardiogram. Two technicians assisted with primary functions of recording the blood pressure and electrocardiogram.

The test was performed on a cycle ergometer (Quinton Instrument, model 845) with a programmer (model 644) enabling automatic progression through the preselected exercise program. A 15 lead electrocardiogram (12 conventional leads plus Frank orthogonal leads X, Y, Z) was recorded using a multichannel recorder (Siemens Mingograf 62). The average of 2 consecutive R-R cycles on the electrocardiogram recorded at a paper speed of 50 mm/s is used for the computation of the heart rate (beats/min). Blood pressure was measured in the right arm of each patient using a programmable air compression cuff system (Narco Biosystem, PE-300) operated by remote control. The guidelines of the Task Force on Blood Pressure Control in Children[8] were followed for selecting the appropriate size compression cuff.

Before exercise, a conventional 12 lead electrocardiogram and Frank orthogonal leads (X, Y, Z) were recorded in the supine and standing positions with and without hyperventilation. Before testing, 3 simultaneous electrocardiographic leads were observed on the oscilloscope for arrhythmia. Heart rate and blood pressure were recorded in the supine position and while sitting on the bicycle ergometer.

During exercise, each patient pedalled at a constant speed (60 to 70 revolutions/min) on the ergometer while the work load increased automatically every 3 minutes. Six electrocardiographic leads (V_1, V_5, V_6, II, X, and Y) were simultaneously recorded every minute. The remaining 9 leads were frequently scanned for changes in the S-T segment. Heart rate was recorded every minute and blood pressure every 1 to 2 minutes. At the peak level of exercise, the electrocardiogram, blood pressure, heart rate, and exercise time were recorded.

Under the protocol, the exercise test was discontinued if 1 or more of the following end points (signs or symptoms) appeared: (1) serious cardiac arrhythmia and conduction disturbance, that is, ventricular tachycardia, premature ventricular complexes greater than 25% of heart rate, supraventricular tachycardia, or induced second or third degree atrioventricular block; (2) S-T depression of 3.0 mm or greater; (3) inappropriate decrease in systolic pressure, that is, 20 mm Hg or greater; (4) exhaustion; and (5) chest pain, dizziness, or pallor.

Cardiac catheterization and angiography: While the patient was sedated in the supine position, the resting left ventricular to aortic systolic gradient was measured from a withdrawal pressure tracing across the obstructed outflow area. Cardiac output was measured in 86% of patients by either the Fick, thermodilution, or cardiogreen method in close sequence to the recording of pressure and before angiography. The anatomy of the valvular and subvalvular areas was determined from the aortogram and left ventriculogram. The severity of aortic incompetence was determined from an interpretation of the aortogram as described by Sellers et al.[9] In this study, 1+ regurgitation is considered trivial and 2+, moderate aortic incompetence.

Data analysis: Total work was calculated as the sum of the products of workload (in kilogram-meters/minute) and exercise time (in minutes) at each level reached in the exercise program. The electrocardiogram was analyzed for (1) S-T depression of 1.0 mm or greater for a duration of at least 60 ms in any lead at peak performance (the baseline for measuring S-T depression is defined as a straight line through the P-R or P-Q junction of 3 to 5 consecutive P-QRS-T complexes)[7]; (2) distribution of the S-T depression; and (3) arrhythmia.

The patients were subdivided into 4 groups according to the magnitude of the resting left ventricular to aortic peak systolic pressure gradient as follows: (1) 29 mm Hg or less (mean 20) in 16 patients (11 male and 5 female) aged 7 to 24 years; (2) 30 to 49 mm Hg (mean 37) in 14 patients (11 male and 3 female) aged 8 to 16 years; (3) 50 to 69 mm Hg (mean 56) in 16 patients (15 male and 1 female) aged 5 to 24 years; and (4) 70 mm Hg or more (mean 105) in 19 patients (15 male and 4 female) aged 4 to 19 years.

Statistical analysis: Mean (± standard error) values for peak exercise heart rate, total work, blood pressure, and magnitude of S-T depression were calculated. The mean values for total work and peak exercise systolic blood pressure were adjusted for the confounding effect of sex, height, and rate of work using analysis of covariance.[7,10] The significance of the difference of means among the control subjects and patient groups were determined by the technique of multiple comparisons. Other mean (± standard error) differences were analyzed by analysis of variance. The frequency of S-T depression of 1 mm or greater was analyzed using the chi-square test.

TABLE I Distribution of S-T Depression of 1 mm or Greater and S-T Segment Slope at Peak Exercise in Control Subjects and Patients With Aortic Stenosis

	n	S-T Segment Slope*			
		Depression	Upward	Horizontal	Downward
Control subjects	164	19	17	2	. . .
Patient groups					
I	16	6	3	2	1
II	14	9	4	5	. . .
III	16	7	3	2	2
IV	19	17	5	10	2

* The S-T segment slope was recorded in the electrocardiographic lead with the greatest amount of S-T depression.

Results

Clinical Data

Group I (resting gradient less than 30 mm Hg): Twelve (75%) of the 16 patients were asymptomatic. Sporadic complaints of chest pain, tiredness, dizziness, and palpitation occurred in the remaining 4 patients. After an interim of 5 years, these 4 patients were asymptomatic and continued to have signs of mild aortic stenosis and trivial to moderate aortic valve incompetence on physical examination.

The resting electrocardiogram was normal in 7 (44%), revealed left ventricular hypertrophy by voltage criteria in 4 (25%), questionable left ventricular hypertrophy in 4 (25%), and left axis deviation in 1 (6%). The chest radiograph was normal in 13 patients (81%), and revealed mild cardiac enlargement in 1 (6%) and a dilated ascending aorta in 2 (13%).

The mean resting systolic gradient was 20 mm Hg with a mean left ventricular pressure of 127/9 and aortic pressure of 107/67. Trivial aortic valve incompetence was present in 9 (56%) and moderate in 2 (13%). The aortic valve was tricuspid in 13, bicuspid in 2, and undetermined in 1 by angiography.

Group II (resting gradient 30 to 49 mm Hg): Eleven (79%) of the 14 patients were asymptomatic and 3 complained of either chest pain or tiredness. The resting electrocardiograms were normal in 9 (64%), and revealed left ventricular hypertrophy in 4 (29%) and questionable left ventricular hypertrophy in 1 (7%). The chest radiograph was normal in 11 (79%), and revealed mild cardiomegaly in 1 (7%) and a dilated aorta in 2 (14%). The mean resting systolic gradient was 37 mm Hg with a mean left ventricular pressure of 137/8 and aortic pressure of 100/66. Trivial aortic valve incompetence was present in 5 (36%) and moderate in 3 (21%). The aortic valve was tricuspid in all patients.

Group III (resting gradient 50 to 69 mm Hg): Ten (62%) of the 16 patients were asymptomatic and 6 (38%) complained of either chest pain, dizziness, or tiredness. The resting electrocardiogram was normal in 4 (25%) and revealed left ventricular hypertrophy in 8 (50%), abnormal S-T segments and T waves in 2 (12.5%) and left axis deviation in 2 (12.5%). The chest radiograph was normal in 8 (50%) and revealed cardiomegaly in 6 (38%) and a dilated ascending aorta in 2 (12%). The mean resting systolic gradient was 56 mm Hg with a mean left ventricular pressure of 163/12 and an aortic pressure of 107/73. Trivial aortic valve incompetence was present in 3 (19%) and moderate in 3 (19%). The aortic valve was tricuspid in 15 patients and bicuspid in 1.

Group IV (resting gradient 70 mm Hg or greater): Five (26%) of the 19 patients denied having symptoms, and 14 (74%) complained of tiredness, chest pain, syncope, or a combination of these. The resting electrocardiogram was normal in 6 (32%) and revealed left ventricular hypertrophy in 11 (58%) and questionable left ventricular hypertrophy in 2 (11%). The chest radiograph was normal in 12 (63%), and revealed cardiomegaly in 5 (26%) and a dilated ascending aorta in 2 (11%). The mean resting systolic gradient was 105 mm Hg with a mean left ventricular pressure of 215/13 mm Hg and aortic pressure of 111/75 mm Hg. Trivial aortic valve incompetence was present in 7 patients (37%). The aortic valve was tricuspid in all patients.

Exercise Data

Electrocardiography (Table I): Significant S-T depression occurred more frequently in the patients than in the normal control subjects ($p < 0.005$). The percentages of exercise-induced S-T depression of 1.0 mm or greater were 38% (6 of 16 patients) in Group I, 64% (9 of 14) in Group II, 44% (7 of 16) in Group III, and 89% (17 of 19) in Group IV. For the 39 patients with S-T depression of 1.0 mm or greater, the mean decreases in the electrocardiographic leads showing the greatest amount of S-T segment change at peak exercise were 1.5, 2.0, 1.8, and 2.4 mm in Groups I, II, III, and IV, respectively (Fig. 1). The S-T segment was horizontal in 49%, upward sloping in 38%, and downward sloping in 13% of the 39 patients with significant S-T depression. The horizontal S-T segment was most common in Group IV, whereas the upward sloping S-T segment was most common in Group I.

Significant exercise-induced S-T depression occurred in the left precordial leads (V_5 and/or V_6) in 35 (90%) of the 39 patients, but was isolated to the left precordial leads in 21 patients (54%). Significant S-T depression was recorded in the inferior leads (II, III, aVF) in 18 (46%) of the 39 patients, but was isolated to

these leads in 4 patients (10%). Fourteen (36%) patients had significant exercise-induced S-T depression in both left precordial and inferior leads. S-T depression of 1 mm or more was recorded in 2 or more leads in 22 patients (56%). In 32 patients (82%), significant exercise-induced S-T depression was detectable in lead V_5. Four patients (6%) had premature ventricular complexes, which necessitated discontinuing the test in 1. In this patient, the premature beats were multifocal with a frequency of more than 25% of the heart rate. In the 4 patients, the occasional ventricular arrhythmia had either a right or left bundle branch block pattern.

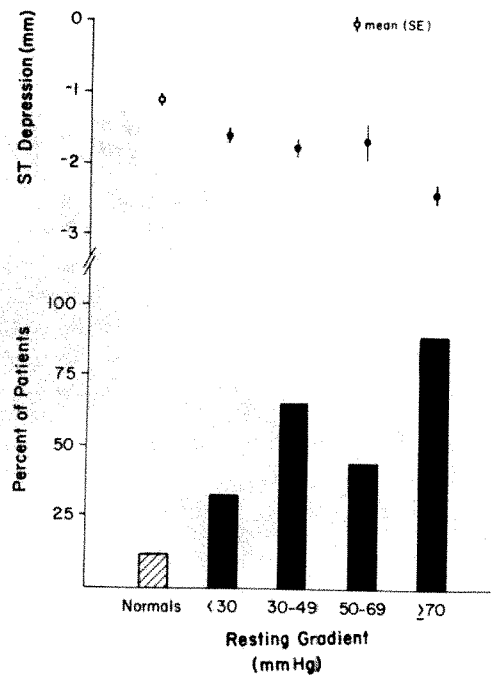

FIGURE 1. Exercise-induced S-T depression in normal subjects and patients with aortic stenosis. The mean frequency and magnitude of S-T depression increases in the patients with an increasing resting left ventricular to aortic systolic pressure gradient. SE = standard error.

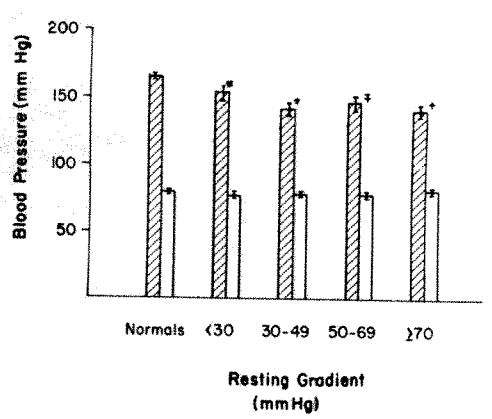

FIGURE 2. Mean (± standard error) peak exercise blood pressure in normal subjects and patients with aortic stenosis. Mean (± standard error) peak systolic pressure is adjusted for body size (height), sex, and work load. Adjusted mean systolic pressure (**hatched bars**) in the patients is significantly lower than normal. Mean (± standard error) peak diastolic pressure (**clear bars**) did not differ significantly among the normal subjects and patients. Levels of significance: *$p < 0.03$; †$p < 0.0001$; ‡$p < 0.0002$.

In the control subjects, the incidence of S-T depression of 1 mm or greater was 12% at peak exercise with a mean magnitude of depression of 1.1 mm. In these patients with S-T depression of 1 mm or greater, the slope of the S-T segment was upward in 89% and horizontal in 11%. Occasional ventricular arrhythmia occurred in 2 (1%) subjects during exercise.

Blood pressure: For each group, the mean (± standard error) pre-exercise supine systolic pressure adjusted for sex and body size (height) was similar to that of the control subjects ($p > 0.1$) (Fig. 2). Also, the mean pre-exercise systolic pressure while sitting on the bike did not differ significantly from that of the control subjects. Mean (± standard error) pre-exercise diastolic pressures in the supine and sitting positions were not significantly different from normal ($p > 0.1$).

During exercise, mean (± standard error) peak-exercise systolic pressures for the patient groups and control subjects were adjusted for the confounding effect of sex, body size (height), and rate of work.[7] In Group I, the adjusted mean (± standard error) peak-exercise systolic pressure (155 ± 4 mm Hg) did not differ significantly from normal ($p > 0.1$). For the other groups, the adjusted mean (± standard error) peak-exercise systolic pressures were 142 ± 5, 151 ± 5, and 148 ± 4 mm Hg for Groups II, III, and IV, respectively, as compared with 161 ± 1 mm Hg for the normal subjects ($p < 0.03$). In all patient groups, mean peak-exercise diastolic pressure was similar to normal ($p > 0.1$).

For each patient in Groups I and II, systolic pressure increased above the pre-exercise level during the exercise test. Systolic pressure during exercise was equal to or less than the pre-exercise systolic pressure in 7 patients, 1 (6%) in Group III and 6 (32%) in Group IV.

Heart rate: Mean (± standard error) pre-exercise heart rates adjusted for sex and body size (height) were 75 to 87 beats/min in the patient groups and normal subjects ($p > 0.1$). Mean (± standard error) peak exercise-heart rates were 190 ± 4 beats/min in Group I, 188 ± 4 in Groups II and IV, and 194 ± 1 in normal subjects. The mean peak heart rate (183 ± 4) in Group III differed significantly from normal ($p < 0.008$) but exceeded 180 beats/min, implying satisfactory effort during the study.

Working capacity: Mean (± standard error) total work (in kilogram-meters) adjusted for the confounding effect of sex and body size (height) was 5,893 ± 858 for Group I, 4,973 ± 925 for II, 3,596 ± 89 for III, 3,851 ± 822 for IV, and 7,600 ± 273 for normal subjects (Fig. 3). Groups II to IV differed significantly from normal with a level of significance of $p < 0.007$, < 0.0001, and < 0.0001, respectively. The adjusted mean (± standard error) highest rate of work (maximal power output, in kilogram-meters/minute) achieved during the test was 776 ± 50 in Group I, 742 ± 54 in II, 590 ± 53 in III, 591 ± 48 in IV, and 878 ± 16 in normal subjects. The level of

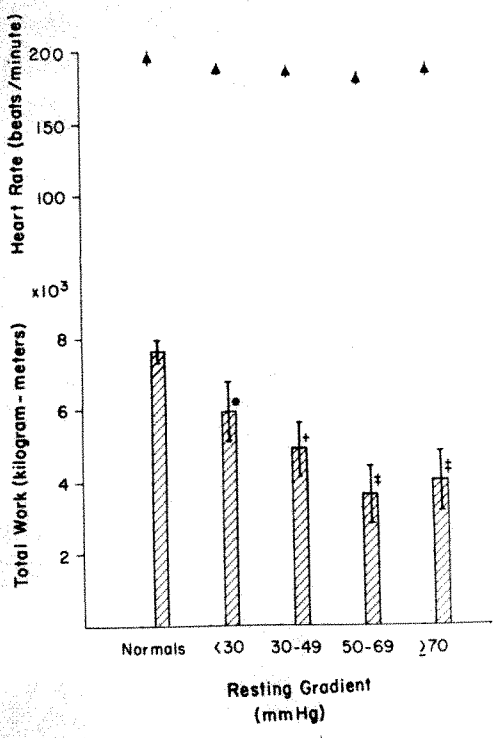

FIGURE 3. Mean (± standard error) working capacity (total work) and peak exercise heart rates in normal subjects and patients with aortic stenosis. After an adjustment for body size (height) and sex, mean (± standard error) total work is significantly decreased in the patients compared with the control subjects. Mean peak exercise heart rates exceeded 180 beats/min in all patient groups and normal subjects. Levels of significance: *p <0.04; †p <0.003; ‡p <0.001.

significance for the difference in maximal power output between each group (I to IV) and normal was $0.06 > p > 0.05$, $p < 0.007$, $p < 0.0001$, and $p < 0.0001$, respectively.

Decreased systolic pressure, total work, and S-T depression: Further analysis was performed to determine the frequency of decreased total work and exercise systolic pressure of −2 standard deviations or more from a normal mean,[7] and S-T depression of 2 mm or greater indicating marked subendocardial ischemia within each patient group (I to IV). S-T depression of 2 mm or more occurred in 74, 31, and 21% in patients of Groups IV, III, and II, respectively. A decreased systolic pressure during exercise and total work occurred most frequently in Group IV at a frequency of 52 and 37%, respectively (Table II). Two or more of the abnormal exercise responses occurred in 47, 25, 29, and 6% of patients in Groups IV, III, II, and I, respectively.

Discussion

This study reveals an increased frequency and magnitude of S-T depression, altered systolic pressure, and decreased working capacity during controlled exercise in children and young adults with valvular or discrete subvalvular aortic stenosis of varying severity. The most abnormal exercise responses occurred in patients with a resting left ventricular to aortic systolic gradient of 70 mm Hg or greater. One or more of these exercise responses was markedly abnormal in 16 of 46 (35%) and 2 or more in 8 of 46 (17%) patients with a left ventricular to aortic systolic gradient less than 70 mm Hg.

TABLE II Frequency of S-T Depression 2 mm or Greater, Systolic Pressure, and Total Work of −2 Standard Deviations or Less at Peak Exercise in Patients

	Group			
	I	II	III	IV
Number	16	14	16	19
S-T depression	. . .	3 (21%)	5 (31%)	14 (74%)
↓ Systolic pressure	4 (25%)	6 (43%)	4 (25%)	10 (52%)
↓Total work	4 (25%)	1 (7%)	5 (31%)	7 (37%)

↓ = decreased.

Exercise Electrocardiogram

Significance: The clinical significance of S-T depression of 1 mm or greater in patients with aortic stenosis is related to other abnormal exercise responses. In our patients with aortic stenosis, S-T depression of 1 mm or greater with normal work and blood pressure at peak exercise suggests mild obstruction with a resting left ventricular to aortic gradient of less than 30 mm Hg. Further, S-T depression of 1 mm or greater with abnormal work and blood pressure at peak exercise suggests significant obstruction with a resting left ventricular to aortic gradient above 30 mm Hg. For healthy children, S-T depression of 1 mm or greater with normal work and blood pressure at peak exercise appears of no clinical significance.

Mechanism: The mechanism for the S-T depression during exercise in the patients with aortic stenosis is thought to be related to an imbalance between myocardial oxygen supply and demand, producing left ventricular subendocardial ischemia. In the control subjects, the mechanism is unclear, but we speculate that strenuous exercise may produce an imbalance between myocardial oxygen supply and demand during the growing period, producing a transient "physiologic" ischemia. Further investigation including longitudinal studies are needed to improve our understanding of the occurrence of S-T depression during exercise in healthy children.

Frequency and predictive value: The frequency of exercise-induced S-T depression of 1 mm or more in our population differed from the studies of Halloran[2] and Chandramouli et al.,[3] who reported that exercise-induced S-T depression of 1 mm or greater indicated a resting left ventricular to aortic systolic gradient greater than 50 mm Hg. In our study, 14 patients with a systolic gradient less than 50 mm Hg had significant exercise-induced S-T depression and 10 patients with a resting systolic gradient greater than 50 mm Hg had no S-T depression during exercise. Using the criteria reported by Halloran,[2] each of the 14 patients had significant exercise-induced S-T depression despite having a resting systolic gradient of less than 50 mm Hg. Simi-

larly, the criteria reported by Chandramouli et al.,[3] which require the S-T segment to be depressed for 80 ms below the baseline, identified significant S-T depression in 11 of the 14 patients. The remaining 3 patients had S-T depression of 1 mm for only 60 ms below the baseline. In contrast to the reported findings of Halloran and Chandramouli, our data do not support using S-T depression to predict the presence of a resting left ventricular to aortic systolic gradient above or below 50 mm Hg in patients. Any further comparison between our study and the series reported by Halloran,[2] Chandramouli,[3] and their co-workers becomes increasingly difficult because of the insufficient data for matching working intensity and the different end points used to discontinue the exercise test.

Factors affecting variability and frequency of S-T depression: Our results suggest that subendocardial ischemia of varying degrees occurs during controlled exercise in patients with aortic stenosis. Further, the degree of ischemia varies in patients having the same or similar resting systolic gradients. The variability may be related to an increased systolic gradient during exercise.[1,11,12] These patients with similar or mild obstruction at rest may have a significantly increased systolic gradient during exercise, causing left ventricular subendocardial ischemia. Since intracardiac pressures were not measured during exercise, this explanation is not confirmed.

Another consideration related to the variability and high frequency of positive S-T depression in patients with a gradient less than 70 mm Hg is the stage of developed hypertrophy at the time of the exercise study. The major stimuli for developing cardiac hypertrophy in this young population are growth and the severity of left ventricular outflow tract disease.[13] The stage of this development probably varies in patients who have so-called mild or similar resting systolic gradients.

The stage of developed hypertrophy and the adaptation to increased cardiac work potentially influence a patient's response to strenuous exercise. In 20 patients who had serial exercise testing between 1 and 5 years, the mean S-T depression in 7 patients (35%) decreased from 1.5 mm during the initial study to 0.5 mm during the follow-up study while performing the same or greater amounts of work. Exercise responses including S-T segment changes are highly reproducible on serial examinations in normal children who have not had physical training and any significant changes in body size.[7] The resolution of the S-T segment in these patients during the longitudinal follow-up may reflect improved adaptation to increased cardiac work, and an improved balance between supply oxygen and demand for oxygen of the myocardium. The S-T depression in the remaining 13 patients increased or was unchanged at the follow-up study. These preliminary findings suggest that significant exercise-induced S-T depression may resolve in certain young patients who have not had the benefit of surgical treatment.

Location of S-T depression: Significant S-T depression was widely distributed (left precordial and inferior leads) in 36% of the patients, suggesting diffuse acute subendocardial ischemia of the left ventricle. Exercise-induced S-T depression was isolated to the left precordial leads (V_4, V_5, and/or V_6) in 54% and to the inferior lead (aVF) in 10%, suggesting regional acute subendocardial ischemia.

The isolated S-T segment depression perhaps reflects the disproportionate increase in wall thickness from pressure-overload[13] of the left ventricle. Experimental data in dogs with left ventricular hypertrophy from aortic banding above the coronary arteries reveal regional maldistribution of myocardial blood flow during exercise.[14,15] The clinical and experimental data suggest that regional subendocardial ischemia probably occurs during exercise in young patients with aortic stenosis and suspected normal coronary arteries.

Blood pressure: Preliminary studies reveal an abnormal rise in systolic pressure occurring in patients with aortic stenosis. Riopel et al.[6] suggest that the difference between exercise systolic and pre-exercise systolic pressure is related to the severity of aortic stenosis. We observed a lower than normal exercise systolic pressure in each of the four patient groups. After an adjustment for sex, body size (height), and rate of work, the difference between the control subjects and patients did not change significantly with increasing gradient. Furthermore, 6 of 19 (32%) patients with a left ventricular to aortic systolic gradient greater than 70 mm Hg had elevated systolic or diastolic pressures, or both.

Mechanism of low exercise systolic pressure: Preliminary data from our laboratory suggest that the mechanism for an abnormally low exercise systolic pressure in patients with a left ventricular to aortic systolic gradient less than 70 mm Hg is a prolonged electromechanical systole.[16] Since the duration of the systole is increased in obstruction,[16] normal or elevated exercise systolic pressure in patients would imply an abnormality of more than one of the determinants of systolic pressure (that is, rate of ejection, stroke volume, and vascular resistance). We suspect that systemic vascular resistance is elevated in patients who have severe obstruction and a normal or elevated exercise blood pressure.

In our study, the systolic pressure during exercise was commonly above the pre-exercise level, but often did not reach the expected level for body size and intensity of work. The exercise systolic pressure fell below or was equal to the pre-exercise value in 6 patients with a left ventricular to aortic systolic gradient above 70 mm Hg. At the same time, the patients had severe S-T depression and the other 3 had chest pain. A fall or lack of rise in systolic pressure during exercise suggested critical obstruction to the left ventricle with a severe compromise in cardiac performance. This response in systolic pressure during exercise was an indication to discontinue the study.

Working Capacity

The amount of work accomplished during the exercise test was inversely related to the resting left ventricular to aortic systolic gradient while mean peak heart

rate exceeded 180 beats/min in each patient group. The exercise test was stopped in 16 patients (25%) because of S-T depression of 3 mm or greater or a fall or lack of rise in exercise systolic pressure, or both, without exercise-induced symptoms. When these 16 patients were omitted from the analysis, total work remained significantly below normal in Groups II, III, and IV ($p < 0.02$, < 0.003, and < 0.007, respectively). In the majority of patients significant abnormal responses were observed during exercise before any symptoms or signs of distress occurred. The quantification of these abnormal changes for known levels of work reveals the severity of the aortic stenosis and the potential benefit of controlled exercise testing in the clinical management of these young patients.

Clinical Symptoms

Twenty (31%) of 65 patients had chest pain, dizziness, or syncope by clinical history as compared with 6 (9%) patients developing symptoms (chest pain or dizziness) during the exercise test ($p < 0.016$). The disparity between the history and the results of the exercise test demonstrate that serious abnormalities reflecting a major compromise in cardiac performance may precede clinical symptoms. In the uncontrolled state, outside the laboratory, the patient is unaware of early abnormalities of myocardial performance and perfusion and may continue physical activity until these abnormalities produce symptoms.

Interpretation of Exercise Tests and Recommendations

A common practice for determining the severity of aortic stenosis is to measure the left ventricular to aortic systolic gradient at rest with or without simultaneous measurement of cardiac output. Although treatment is not standardized, patients with a left ventricular to aortic systolic gradient exceeding 70 mm Hg and in some instances of less magnitude[4] are generally recommended for surgical relief of the obstruction.

This study identifies patients previously judged to have mild obstruction whose exercise response simulates that found in patients with a left ventricular to aortic systolic gradient of 70 mm Hg or greater. We previously showed that patients having marked S-T depression and decreased total work or exercise systolic pressure, or both, benefit from surgery.[4] After surgery, the improvement in exercise responses may take several months and is partly related to favorable changes in oxygen transport, myocardial performance, and perfusion.

Patients with a slightly abnormal exercise response should be followed up to determine the persistence or progression of the abnormal responses. Progression of abnormal changes during longitudinal follow-up indicates progressive disease and warrants an evaluation by cardiac catheterization and possibly surgical treatment. Although measurement of the gradient remains essential for identifying severe left ventricular outflow tract obstruction, this study demonstrates that exercise testing reveals serious abnormalities of left ventricular performance and perfusion in patients otherwise classified as having moderate or even trivial obstruction.

Safety: This study expands the data base demonstrating that exercise testing can be performed at low risk in children with significant aortic stenosis. A satisfactory system for monitoring several electrocardiographic leads and blood pressure, particularly systolic pressure, is mandatory. Further, properly trained personnel including a physician to evaluate and interpret signs, symptoms, and exercise responses are required to increase the yield and safety of the exercise test.

Mechanism of Acquired Right Ventricular Outflow Tract Obstruction in Patients With Ventricular Septal Defect: An Angiocardiographic Study

GIACOMO PONGIGLIONE, MD, ROBERT M. FREEDOM, MD, FRCP(C), DAVID COOK, MA, and RICHARD D. ROWE, MD, FRCP(C)

Right ventricular outflow tract obstruction can complicate the natural history of patients with isolated ventricular septal defect. Although numerous pathologic mechanisms may be responsible for this phenomenon, it is less clear what the frequency is of each of these mechanisms in any cohort of patients studied in a single institution. We identified 20 patients with isolated ventricular septal defect from 1970 to 1981 who acquired a right ventricular outflow tract gradient of 25 mm Hg or more. They ranged in age at the initial catheterization investigation from 4 days to 23 months and at the subsequent study from 13 months to 8 years. Angiographically, 2 mechanisms were implicated in the 20 patients. Hypertrophy of right ventricular anomalous muscle bundles was identified in 19 of the 20 while hypertrophy of a malaligned infundibular septum (that is, classic tetralogy type) was identified in only 1 patient. These data indicate that acquired right ventricular outflow tract obstruction is rarely of the classic tetralogy type.

It is well known that right ventricular outflow tract obstruction may be an acquired phenomenon in some patients with ventricular septal defect and that it can irrevocably alter the patient's natural history. Since the report of Gasul et al.[1] in 1957 on the development of infundibular obstruction in patients with a ventricular septal defect and the subsequent transformation of their conditions into the cyanotic or acyanotic types of "tetralogy of Fallot," a large body of literature has accumulated concerning the incidence and potential mechanisms of this occurrence. Indeed, the report of Weidman et al.[2] on the Joint Study on Congenital Heart Disease suggests that the incidence of acquired right ventricular outflow tract obstruction is about 3%,[3] while the study of Corone et al.[4] suggests a somewhat higher incidence of 7%. A number of small series and case reports have examined the mechanisms of this acquired right ventricular outflow tract obstruction in patients with ventricular septal defect. Although multiple mechanisms have been implicated, there appear to be primarily 2 mechanisms by which right ventricular outflow tract obstruction and ventricular septal defect can be acquired: (1) hypertrophy of right ventricular anomalous muscle bundles, and (2) hypertrophy of a malaligned (anterosuperiorly deviated) infundibular septum as seen in the tetralogy of Fallot malformation. The purpose of our study is to document angiographically the mechanism responsible for acquired right ventricular outflow tract obstruction in 20 patients with ventricular septal defect studied in 1 institution.

Nomenclature

Ventricular septal defect: There is no unanimity regarding the nomenclature of ventricular septal defect. We will utilize in this study the nomenclature advocated by Soto et al.[5] Again, this is an angiographic study, and we will attempt to define the ventricular septal defect as membranous (or perimembranous), muscular, or subarterial.

A perimembranous ventricular septal defect is one involving the membranous septum and extending into the contiguous muscular septum. Part of the rim of the defect is formed by the central fibrous body. This defect may extend into the inlet, trabecular, or infundibular portions of the septum.

A muscular ventricular septal defect has pure muscular rims and may be located in the inlet, trabecular, or infundibular portions of the ventricular septum.

A subarterial ventricular septal defect has a totally deficient infundibular septum so that the aortic and pulmonary valves are contiguous in the root of the defect.

Various terms have been used to characterize the mechanism considered responsible for acquired right ventricular outflow tract obstruction. Thus, it may therefore be difficult to ascertain the true morphologic basis for such obstruction. Terms such as *prominent crista supraventricularis*,[6,7] *low infundibular stenosis*

with infundibular chamber,[6] *narrow and hyperdynamic infundibulum,*[6,8] *anomalous muscle bundles,*[9,10] and double-chambered right ventricle[11] are often encountered and because of their imprecision may be confusing. We have tried to be very specific in our identification and distinction between true tetralogy anatomy (malalignment between infundibular septum and trabecula septomarginalis) and nontetralogy-like mechanisms.

Anomalous muscle bundles: Anomalous right ventricular muscle bundles may be considered an abnormally positioned and hypertrophied moderator band. As such, they can occur in a high or low position, depending on the site of insertion of the moderator band and on the inclination of the moderator band itself. If the insertion of the moderator band on the septal band is in a higher and more posteromedial position, the anomalous muscle bundle will be closer to the inlet of the right ventricle. There is a continuum of possible points of insertion of the moderator band onto the septal band.[10,11]

The angiographic diagnosis of anomalous muscle bundle has been made according to the criteria of Fellows et al.[9] The obstruction to pulmonary blood flow is determined not only by the actual amount of muscular hypertrophy, but perhaps by the position of the anomalous muscle bundle.[11]

Angiographically, the anomalous muscle bundle takes the form of 1 or more radiolucent bands crossing the right ventricular cavity with a diagonal orientation at a higher or lower level. In its most severe forms, it consists of a pyramidal filling defect with the base broadly attached to the anterior free wall of the right ventricle and with the apex protruding superiorly and posteriorly close to the septal band and the tricuspid ring[9–11] (Fig. 1).

Hypertrophy of os infundibular muscle bundles with stenosis of the os infundibulum may produce right ventricular outflow tract obstruction. Isolated stenosis at this level can be differentiated from classic tetralogy of Fallot.[9] Angiographically, this form of obstruction takes the form of a discrete narrowing of the proximal infundibulum (Fig. 2).

Tetralogy of Fallot: The morphologic (and angiographic) essence of tetralogy of Fallot is anterosuperior deviation or malalignment of the infundibular septum from the limbs of the trabecula septomarginalis.[12–14] This cephalad deviation results in actual or potential subpulmonary muscular obstruction with the ventricular septal defect below the malaligned septum. When the obstruction is low infundibular the length of the infundibulum is generally normal and its width is normal above the obstruction or only minimally decreased. When both the infundibular septum and the anterior infundibular wall are also hypertrophied, the infundibulum is often diffusely narrowed.[12]

The angiographic recognition of a malaligned infundibular septum has been made according to the criteria of Bargeron et al.[14] It is known that some patients will exhibit right ventricular outflow tract obstruction resulting from both a malaligned infundibular septum and anomalous muscle bundle. In these cases, the mid- or the apical portion of the trabecular septomarginalis are usually hypertrophied.[15]

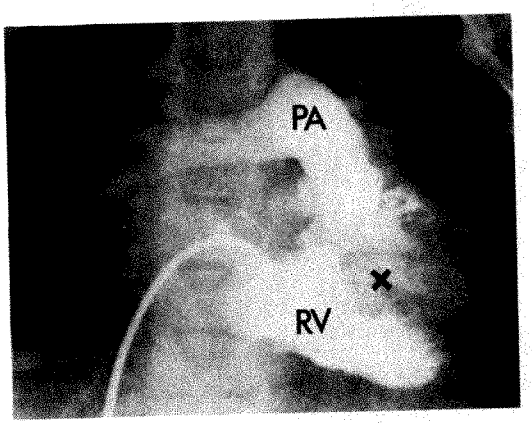

FIGURE 1. Anomalous right ventricular muscle bundles. Frontal right ventriculogram demonstrates an abnormal muscular bar (X), which is pyramidally shaped and divides the inlet from the outlet or infundibular zone of the morphologic right ventricle (RV). PA = pulmonary artery.

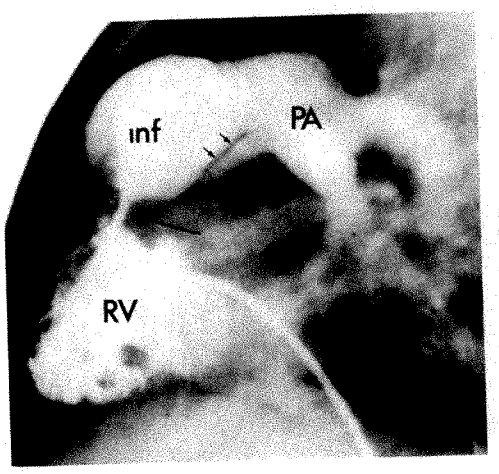

FIGURE 2. Isolated stenosis of the ostium of the right ventricular infundibulum. This lateral right ventriculogram shows a very severe concentric muscular stenosis (**large black arrow**) of the proximal infundibulum. The infundibular chamber (inf) is well demarcated. The pulmonary valve leaflets (**small black arrows**) are slightly thickened. Abbreviations as in Figure 1.

Methods

Patient selection: All hemodynamic and angiographic data were obtained from patients studied in the cardiac catheterization laboratory of the Hospital for Sick Children, Toronto, Ontario, Canada. From 1970 through 1981, we identified 20 patients with ventricular septal defect in whom right ventricular outflow tract obstruction was acquired. Their angiocardiographic findings form the basis for this report. During the same interval, about 2,541 patients with isolated ventricular septal defect were assessed clinically at this institution. All patients had levocardia, atrial situs solitus, and a "right-handed" ventricular loop with atrioventricular and ventriculoatrial concordance. Criteria for inclusion in the study included a right ventricular to pulmonary artery pressure gradient of 15 mm Hg or less at the first catheterization study and a pressure gradient of 25 mm Hg or more at the subsequent investigation.

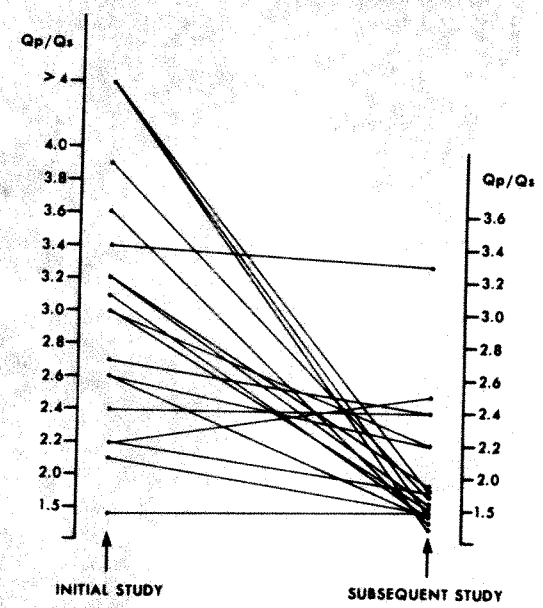

FIGURE 3. Graph depicting the change in pulmonary to systemic blood flow ratio (QP/QS) from the initial catheterization study to the subsequent study.

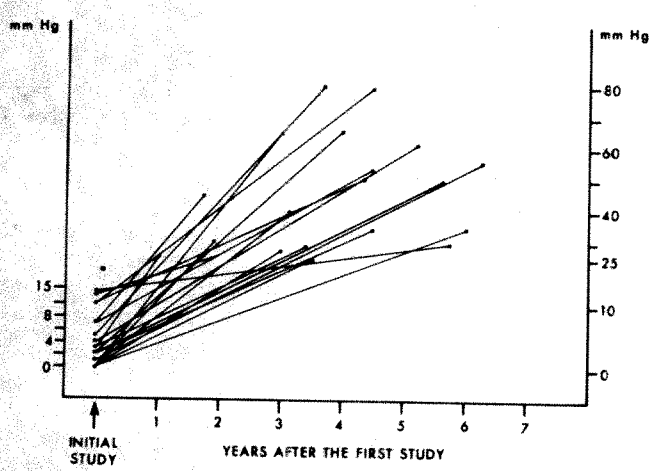

FIGURE 4. Graph demonstrating the acquisition of right ventricular outflow tract obstruction over the same time course as in Figure 3. The **vertical axes** indicate the maximal systolic pressure gradient between the right ventricle and pulmonary artery.

Angiocardiography: All patients had left ventricular angiograms performed in either the left anterior oblique or elongated axial views as advocated by Bargeron et al.[16] at the first catheter study; the left ventricle was approached either through a foramen ovale defect or retrograde from the femoral artery. Two patients had right ventricular angiograms at the initial study. At the second catheter study all patients had frontal and lateral biplane right ventricular cineangiocardiograms, and biplane left ventriculograms were again performed in all patients using the left and right anterior oblique or the elongated axial projections.

Hemodynamics: Complete hemodynamic data were obtained in all patients before angiography. Pulmonary to systemic flow ratios were calculated using either oximetry data or forward dye curves. All pressure data were obtained using fluid-filled catheters interfaced with a Hewlett-Packard 889A system.

Results

Twenty patients were identified from 1970 to 1981 who satisfied the criteria of acquiring a right ventricular outflow tract gradient of 25 mm Hg or more. There were 15 boys and 5 girls. The age at the initial catheterization study ranged from 4 days to 23 months (median 3 months, mean 4.4 months + 5.3 [standard deviation]), and at the second study from 13 months to 8 years (median 4.54 months, mean 4.34 ± 1.64). The time elapsed between the 2 investigations was 3 years 10 months ± 1 year 6 months.

Hemodynamics: Systemic arterial oxygen saturation was normal in each patient at the initial investigation. The pulmonary to systemic flow ratio ranged from 1.4:1 to 7.5:1 (median 3.05:1, mean 3.12 ± 1.3). At the second investigation, only 15 percent of patients had evidence of systemic arterial desaturation (less than 95%), and in these patients the oxygen saturation ranged from 92 to 94%. In the remainder of the patients arterial blood saturation was normal at the second investigation. The pulmonary to systemic flow ratio at this study ranged from 1.2 to 3.4 (mean of 1.8 ± 0.5, median 1.75) (Fig. 3).

All patients had a right ventricular outflow tract pressure gradient at the initial catheter study of 15 mm Hg or less (despite large shunts). The right ventricular outflow tract pressure gradients ranged from 0 to 14 mm Hg (mean 4.15 ± 4.5, median 2.4), with 17 of the 20 patients having an initial right ventricular to pulmonary artery gradient of less than 10 mm Hg. The second investigation revealed that the right ventricular outflow tract obstruction gradients had increased, ranging from 25 to 80 mm Hg (mean 45.6 ± 18.1, median 42.5) (Fig. 4). The pressure in the right ventricle ranged from 20 to 75 mm Hg at the first catheterization (median 47.5; mean 53.6 ± 14.0) and from 46 to 110 mm Hg (median 78, mean 70.1 ± 30.7) at the following study.

Left ventricular angiography: The ventricular septal defect was perimembranous in all, but extended to and was confluent with an infundibular or subarterial ventricular septal defect in 4 patients or extended posteriorly and involved the muscular inlet septum in 12 patients. One patient had multiple ventricular septal defects (perimembranous and small muscular trabecular ventricular septal defects). No patient had swiss-cheese defects. A so-called aneurysm of the perimembranous ventricular septum was not identified in any patient at the initial investigation, and at the subsequent study 3 aneurysms were demonstrated (15%). The gradient across the right ventricular outflow tract in these patients ranged from 0 to 7 mm Hg at the first study and from 27 to 50 at the second one. No patient showed hemodynamic or angiocardiographic evidence of left ventricular outflow tract obstruction during the course of this study.

Right aortic arch was identified in 3 patients (15%). Their gradient across the right ventricular outflow tract was 3 to 7 mm Hg at the first study and 29 to 62 mm Hg at the subsequent one.

Right ventricular angiography: We identified angiographically only 2 mechanisms responsible for

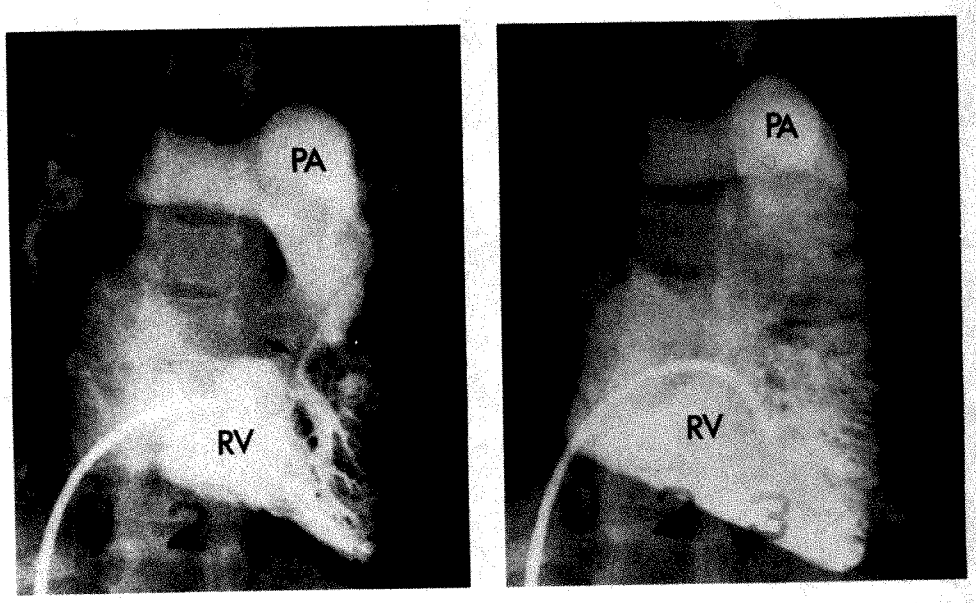

FIGURE 5. Angiographic appearance of hypertrophied right ventricular muscle bundles (**arrow**) in systole (**left**) and diastole (**right**). Abbreviations as in Figure 1.

acquired right ventricular outflow tract obstruction in the setting of isolated ventricular septal defect. Among the 20 patients included in this study, the morphologic basis for acquired right ventricular outflow tract obstruction was identified as being secondary to hypertrophy of right ventricular anomalous muscle bundles in 19. As noted earlier, right ventriculograms were performed in only 2 patients at the initial investigation because their pressure gradient across the right ventricular outflow tract was small and was attributed to the high pulmonary blood flow. Thus, we are unable to state with certainty whether right ventricular muscle bundles (amomalous or not) were present at the initial study, and that their hypertrophy over time led to subsequent right ventricular outflow tract obstruction. Conversely, the other explanation is de noveau development and hypertrophy of anomalous muscle bundles as the cause of the obstruction. We think that a malaligned infundibular septum is, of course, congenital in origin, but that its hypertrophy resulted in the evolution of the obstructive phenomenon.

Anomalous muscle bundles are easily demonstrated during ventricular systole but are less conspicuous during diastole[10] (*Fig. 5*). There is considerable heterogeneity among the angiographic appearances of right ventricular muscle bundles, and our patients exhibited the entire spectrum. In some patients the obstruction appeared primarily in the os infundibulum (but without malalignment of the infundibular septum), while in others there was a classic appearance of a hypertrophied or possibly misplaced moderator band clearly separating the inlet of the right ventricle from the outlet zone. Many patients exhibited combinations of both features with extensive hypertrophy of the apical trabecular zones as well. Only 1 patient was identified as showing the classically malaligned infundibular septum consistent with the classic tetralogy of Fallot. This patient also demonstrated heavy septal trabeculation, but this is considered typical of the usual type of tetralogy of Fallot.

No patient exhibited pulmonary valvular stenosis as the primary cause of acquired right ventricular outflow tract obstruction. Five patients, however, did show evidence of a somewhat thickened pulmonary valve at the second catheterization.

Aortic valve deformities: Aortography was performed in 11 patients at the initial study, and at the subsequent investigation 16 patients underwent retrograde aortography. We were surprised to find that 10 patients demonstrated aortic valve prolapse to a mild or moderate degree. Prolapse of the noncoronary cusp occurred in 1 patient; 5 patients had prolapse of the right cusp, 1 of the left, and 3 of the right and posterior cusps. The prolapsing cusp(s) resulted in mild aortic valve regurgitation in 4 patients.

Surgical correlates: Thirteen of these 20 patients have undergone open heart surgery, with closure of the ventricular septal defect in all cases and repair of right ventricular outflow tract obstruction. In each patient the angiographic type of right ventricular outflow tract obstruction was confirmed.

Discussion

Mechanisms of acquired right ventricular outflow tract obstruction: Several morphologic mechanisms can lead to acquired right ventricular outflow tract obstruction in patients with an isolated ventricular septal defect. They include, singly or in combination: (1) hypertrophy of malaligned infundibulum (so-called tetralogy-type); (2) anomalous right ventricular muscle bundles; (3) so-called wind-sock aneurysm of membranous septum[17]; (4) development of a subpulmonary fibrous diaphragm[18,19]; (5) accessory tricuspid leaflet[20]; (6) neoplasm[21]; and (7) other.[22] Numerous case reports have identified the mechanism responsible for acquired right ventricular outflow tract obstruction in 1 or a few patients. However, it is unclear what mechanisms are most frequently responsible for acquired right ventricular outflow tract obstruction in any cohort of patients studied in a single institution. One could assume

that either a tetralogy-type of right ventricular outflow tract obstruction or anomalous muscle bundles should be the most prevalent mechanism. Rather, the focus of attention of the "natural history" studies is on the incidence of this phenomenon rather than the mechanism. Previous reports frequently refer to acquired right ventricular outflow tract obstruction as a "tetralogy-like" phenomenon, and one could not dispute this in terms of the hemodynamic evolution. However, our data strongly support the view that acquired right ventricular outflow tract obstruction in patients with an isolated ventricular septal defect is rarely of the classic tetralogy-type. Rather, the obstruction seems to result from hypertrophy of right ventricular muscle bundles, whether anomalous or not. Although in our series 1 of 20 patients (5%) had right ventricular outflow tract obstruction due to infundibular malalignment, could our data, because of a small patient population, have underestimated its true frequency? Statistical analysis using the standard binomial formula[23] suggests that our results would be improbable ($p = 0.025$) if malalignment caused more than 25% of cases and unlikely ($p = 0.1$) if it caused more than 17.5% of cases.

Varghese et al.[6] reviewed the natural history of 14 patients with ventricular septal defect and right aortic arch with particular emphasis on the incidence of and mechanisms responsible for acquired right ventricular outflow tract obstruction. Their data suggest that in 6 patients anomalous muscle bundles seemed responsible for the acquisition of right ventricular outflow tract obstruction, whereas in 2, the obstruction was of a more classic tetralogy type. Two other cases presented unclear characteristics.

Right ventricular anatomic considerations: Considerable attention has previously been focused on the disposition of muscle bundles in the apical trabecular and infundibular zones of the normal as well as the abnormal right ventricle. What is unclear from our data is whether right ventricular outflow tract obstruction can be acquired in the presence of a "normal" right ventricular myocardial matrix, or whether even in the absence of a pressure gradient, right ventricular myocardial abnormalities may be present which have the late potential for hypertrophy and obstruction. In this regard, we presented elsewhere[24] persuasive angiographic evidence that fatal subaortic stenosis can develop rapidly in an infant previously shown to have an angiographically normal left ventricular outflow tract.

Among our 20 patients, 2 had right ventricular cineangiocardiograms at the initial catheter investigation, and 1 of these was considered entirely normal. The second one presented an enlarged right ventricle and features of transient myocardial ischemia. We were not impressed with the angiographic appearance of the disposition of right ventricular muscle bundles, or the potential for evolution into obstruction. Furthermore, although Tyrrell et al.[25] and others[9] have commented on the horizontal geometry of the pulmonary artery as a harbinger of acquired right ventricular outflow tract obstruction in patients with ventricular septal defect, this finding was absent in our group of patients.

Acquired subaortic stenosis was not found in this particular group of patients, although like Baumstark et al.[26] we have also observed this occurrence in patients with ventricular septal defect and right ventricular anomalous muscle bundles. We were surprised by the high incidence of aortic valve deformities in our group of patients, most of whom did not have infundibular subarterial ventricular septal defects.

We conclude that in patients with isolated ventricular septal defect acquired right ventricular outflow tract obstruction usually results from hypertrophy of anomalous muscle bundles.

CONFERENCE ON

"CLINICAL ASPECTS OF LIFE-THREATENING ARRHYTHMIAS"

Palazzo dei Congressi **Florence, Italy** **June 17–18, 1983**

The conference is co-sponsored by The New York Academy of Sciences and The Center for Clinical Physiology and Hypertension of the University of Milan. The conference chairmen are: Henry Greenberg (Columbia University); Henri Kulbertus (University of Liege); Arthur Moss (University of Rochester); and Peter Schwartz (University of Milan).

The purpose of the conference is to provide a forum for investigators from the international scientific community to critically survey the present state of knowledge and to discuss future avenues of clinical research in malignant ventricular arrhythmias. The conference will address three main topics: Electrophysiology, Pharmacology and Clinical Aspects of Patient Management. There will be 20 formal papers and 4 panel discussions. Papers will be presented in English with simultaneous translation into Italian.

Inquiries should be addressed to: Conference Director, The New York Academy of Sciences, 2 East 63rd Street, New York, New York 10021.

FOR CONTROL OF ELECTROCARDIOGRAM ARTIFACTS

FRA STRESS TEST SHIRT is an omnidirectional stretchable net shirt that secures electrodes and lead cables to the body of the patient during an electrocardiogram.

FRA STRESS TEST SHIRT offers the following advantages:

— soft yet firm compression. Cables do not move when the patient is running on the treadmill. Electrodes stay in place even if they are loosened.

— perfectly washable and reusable.

— avoids hair cutting, taping or bandaging.

— remains comfortable while it allows freedom of movement. There is no possibility of muscular tremor, jitters or baseline wandering.

— one size fits all.

— individually packaged in boxes of 12 each.

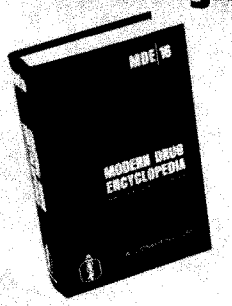
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

Yorke Medical Books
Box C-757, Brooklyn, New York 11205 AJCJ2

Please send me a copy of the all-new 16th Edition of MODERN DRUG ENCYCLOPEDIA. If this new edition is the best drug information reference for practitioners available, I will remit $49.00 plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ I am enclosing $49.00 now as full payment.

Norpace
(disopyramide phosphate) 100-mg and 150-mg capsules

Norpace CR controlled release
(disopyramide phosphate) 100-mg and 150-mg capsules

Before prescribing Norpace (disopyramide phosphate) or Norpace CR, please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Norpace CR should not be used initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide phosphate has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace or Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace or Norpace CR, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or Norpace CR should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace or Norpace CR should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace or Norpace CR considered. In rare instances significant hypoglycemia has been reported during Norpace or Norpace CR therapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace or Norpace CR should be reduced. If the block persists, continuation of Norpace or Norpace CR must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or trifascicular block requires discontinuation of Norpace or Norpace CR, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of disopyramide phosphate. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Norpace CR is not recommended for patients with severe renal insufficiency. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of labor and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory difficulty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses. The recommended dosage schedule for most adults is either 150 mg every six hours for immediate-release Norpace or 300 mg every 12 hours for Norpace CR. For patients less than 110 pounds (50 kg) the recommended dosage is either 100 mg every six hours for immediate-release Norpace or 200 mg every 12 hours for Norpace CR. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg of immediate-release Norpace every six hours, with subsequent dosage adjustments made gradually with close monitoring. **See current complete prescribing information for dosage recommendations, including pediatric use.**

New Norpace® CR controlled release

(disopyramide phosphate)

100-mg and 150-mg capsules

Simple dosage schedule *Just two capsules b.i.d. reduce the potential for skipped doses.*

Enhanced compliance *Norpace CR helps to establish continuous effective dysrhythmia therapy... especially well suited to long-term use.*

Effective dysrhythmia therapy *Bioavailability studies demonstrate that Norpace CR q12h provides therapeutic blood levels equivalent to immediate-release Norpace (disopyramide phosphate) q6h, with less variability.*

The most commonly seen side effects from disopyramide phosphate are anticholinergic, and the most severe are due to its negative inotropic properties. Please see the brief summary of prescribing information on the preceding page.

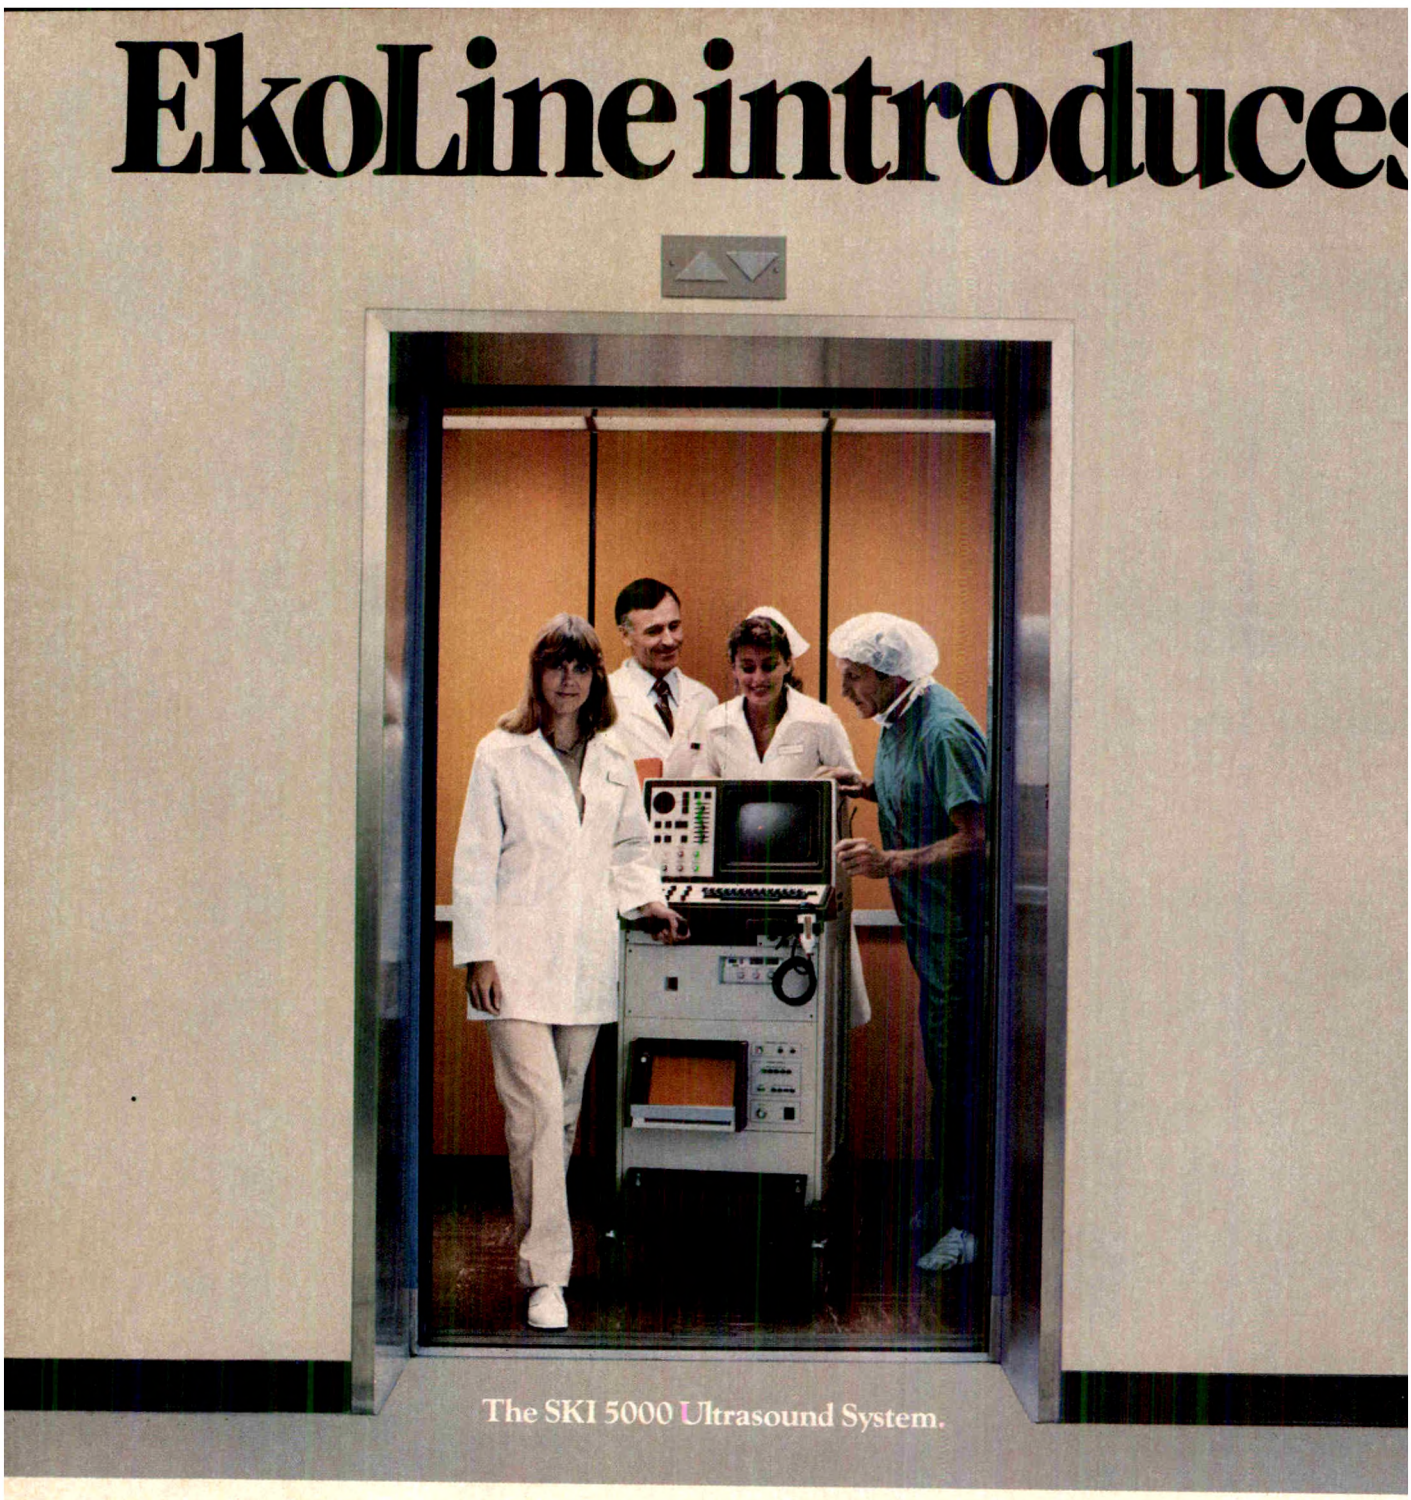
EkoLine introduces



The SKI 5000 Ultrasound System.

The new super-portable SKI 5010 has the same advanced sector image as the SKI 5000- and less.

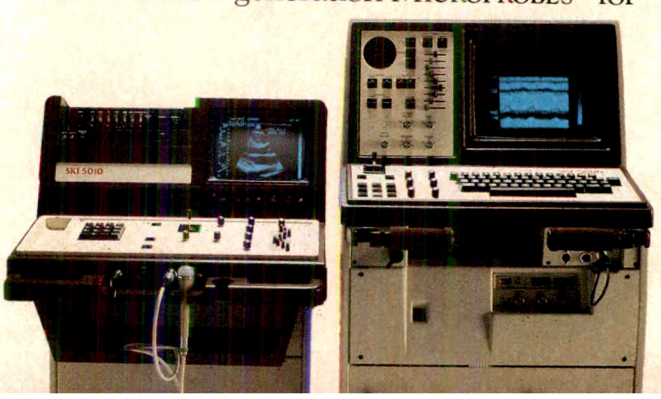
Less size.

Less weight.

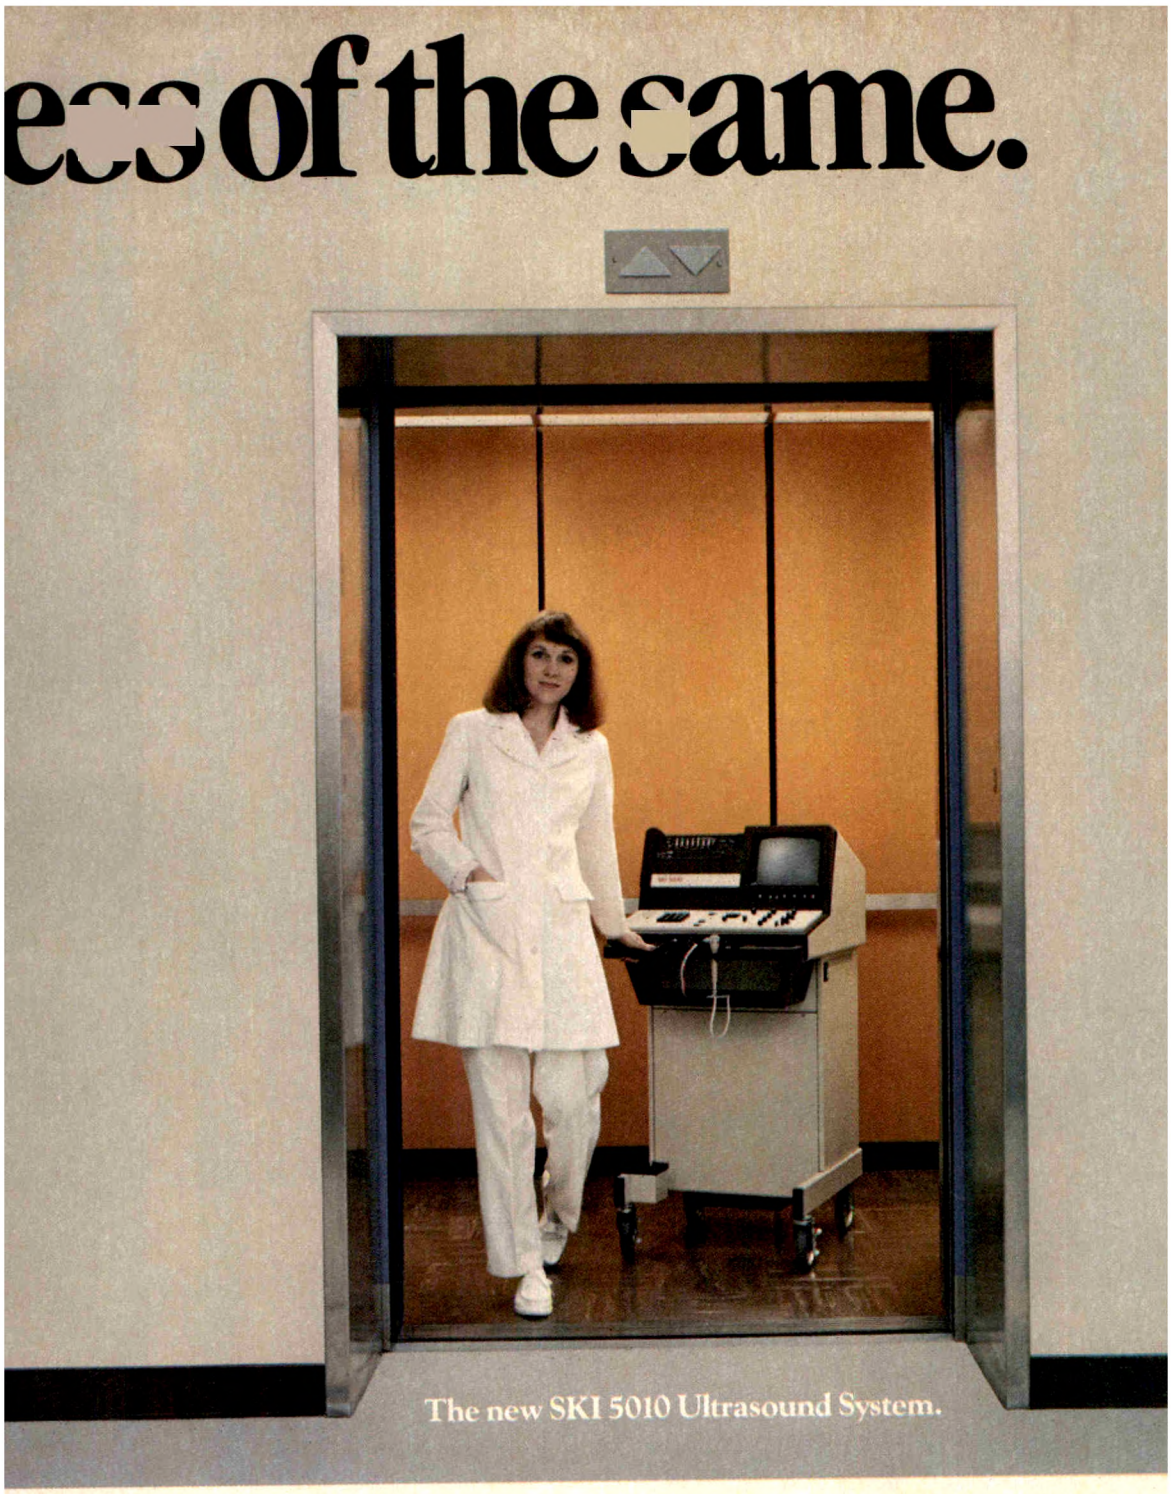
Less cost.

Of course, it has a few less features than the SKI 5000. But it still has the same superior M-mode, manual TGC with nine separate slide controls, and a video tape recorder that produces compatible tapes with other recorders like the one in the SKI 5000.

In addition, the SKI 5010 will accommodate all new generation MICROPROBES™ for



ecs of the same.



The new SKI 5010 Ultrasound System.

M-mode or sector imaging. For more information about the new SKI 5010 or the SKI 5000, send coupon today. Or call toll-free (800) 538-1556. In California, (408) 732-6010. EkoLine, Inc., 880 West Maude Avenue, Sunnyvale, CA 94086.

DIGITALIS TOXICITY
- and how to avoid it in CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

furosemide BRAND OF

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.

But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic.*

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.

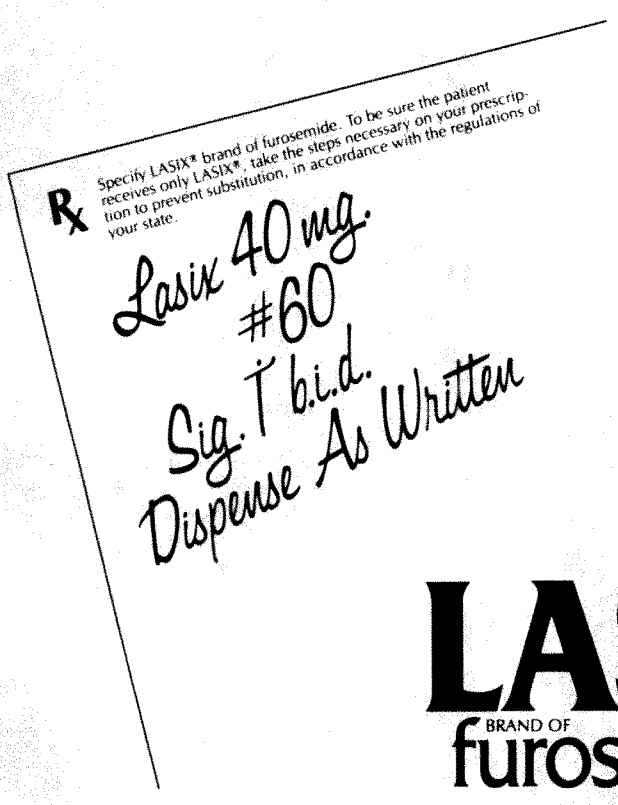
Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration... and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.



If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

LASIX®

TABLETS: 20, 40 & 80 mg

furosemide BRAND OF

The diuretic of choice for the digitalized patient.

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Surgical Repair of Congenitally Corrected Transposition of The Great Arteries: Results and Follow-Up

BETAU HWANG, MD, FREDERICK BOWMAN, MD, JAMES MALM, MD, and EHUD KRONGRAD, MD

Eighteen patients with congenitally corrected transposition of the great arteries had open heart repair for intracardiac associated defects. Fourteen patients (78%) are alive during the follow-up period (mean 4.5 years). Seventeen (94%) of the 18 patients had ventricular septal defect closure, and 12 (66%) insertion of a pulmonary artery conduit. Surgical repair of the tricuspid valve was required in 6 patients (33%) during the first operation and in 3 additional patients during a second operation (total 50%). When hemodynamic overload or cardiac compromise was detected after surgery it was directly related to identifiable residual defects such as atrioventricular valvular insufficiency, residual ventricular septal defect, or pulmonary conduit stenosis. Repeat open heart operation for residual defects was common during the follow-up period (8 of 18 patients, 44%). No patient showed primary systemic or pulmonary ventricular dysfunction during the follow-up period. None of the last 11 patients developed complete heart block. Postoperative intraventricular conduction defects were common and are presumably caused by surgical injury of the bundle branches.

Our observations suggest that surgical repair of congenitally corrected transposition of the great arteries can be currently achieved with acceptable risk. Improved knowledge of the precise location of the specialized conduction system resulted in a marked decrease in the incidence of atrioventricular (A-V) block in patients with congenitally corrected transposition of the great arteries undergoing intracardiac repair. In the absence of postoperative residual defects it can be expected that longevity and quality of life will improve considerably, but many of these patients may require a repeat operation.

Congenitally corrected transposition of the great arteries is an uncommon congenital malformation of the heart. It is a congenital malformation with arterioventricular discordance in which the anatomic right ventricle is usually on the side opposite that occupied by the liver and the aorta emerges from the anatomic right ventricle and is placed anterior and usually leftward to the pulmonary artery. Surgical experience with congenitally corrected transposition of the great arteries to this date has been limited. Complete surgical repair is usually associated with high mortality, high morbidity, and a high incidence of surgically induced complete heart block.[1-3] In general, early and late results were less favorable when compared with outcome achieved after repair of other congenital cardiac malformations. Further, concern has been raised regarding the postsurgical status of the left-sided (anatomic right) ventricle and its tricuspid valve and their long-term ability to function well under systemic pressure.[2] This report presents our experience and the outcome of open heart repair in patients with congenitally corrected transposition of the great arteries.

From the Department of Pediatrics, Pediatric Cardiology, Babies Hospital and the Surgical Service of Presbyterian Hospital and the College of Physicians and Surgeons, Columbia University, New York, New York. Manuscript received January 26, 1982; revised manuscript received February 12, 1982, accepted April 16, 1982.

Address for reprints: Ehud Krongrad, MD, Department of Pediatrics, Babies Hospital, 3959 Broadway, New York, New York 10032.

Methods

Patient population: During the years 1969 to 1980, 41 patients at Columbia-Presbyterian Medical Center had various forms of open or closed surgical treatment for congenitally corrected transposition of the great arteries with 2 ventricular

chambers. Eighteen of the 41 had open heart repair and are the subject of this report, and 23 additional patients had various closed procedures. The patients' age at the time of open heart surgery ranged from 6 to 38 years (median 13). Fourteen patients were male and 4 were female. A total of 26 open heart procedures were carried out in these 18 patients. Fourteen (78%) of the 18 patients are alive, and their follow-up period ranged from 11 months to 10.5 years (median 4.5).

Various types of open heart procedures utilized to repair the intracardiac defects (Table I): Eight patients had ventricular septal defect closure and insertion of a pulmonary artery valved conduit. Four patients had closure of a ventricular septal defect and left side atrioventricular (A-V) valve repair during the first open heart operation. Three of these 4 patients required valve replacement and in 1 patient tricuspid (left A-V valve) valvuloplasty was carried out. Three patients required plication of a membranous septal aneurysm including closure of a ventricular septal defect.[4] Two of these 3 patients required in addition a pulmonary valved conduit, and 1 patient required pulmonary infundibulectomy. One patient had closure of a ventricular septal defect, insertion of a pulmonary artery valved conduit, and left A-V valve replacement. Two additional patients had open heart surgery. The first had left-sided A-V valve replacement alone and the other had ventricular septal defect closure, placement of a pulmonary artery valved conduit, and right-sided A-V valve replacement. Thus, 17 of the 18 patients had ventricular septal defect closure, 12 had insertion of a pulmonary valve conduit and 6 had left sided A-V valve repair or replacement during the first open heart procedure.

Additional open heart surgery was subsequently carried out in 8 patients (Table II). Two patients required closure of a residual ventricular septal defect; 2 patients subsequently had left-sided A-V valve replacement. One patient had left sided A-V valve anuloplasty and an additional patient had right sided A-V valve anuloplasty. Two patients required replacement of a stenotic pulmonary ventricle to pulmonary artery valved conduit.

Mapping of atrioventricular conduction: Intracardiac mapping for delineation of the His bundle was carried out in 11 of the 18 patients (Table III). After intracardiac mapping 2 of the 11 patients developed transient prolongation of the P-R interval on the electrocardiogram, and there was no change in A-V conduction in the other 9 patients. During this time open heart repair was carried out in 7 additional patients without the aid of intracardiac mapping. Of the 7 patients without intracardiac mapping 1 developed prolonged P-R interval, 2 patients developed permanent complete A-V block, and 1 patient developed transient complete A-V block.

TABLE I Surgical Procedures Employed During First Open Heart Repair in 18 Patients With Congenitally Corrected Transposition of the Great Arteries

VSD closure + PA valved conduit	8
VSD closure + left A-V valve repair	4
Plication of membranous septal aneurysm	3
VSD closure + PA conduit + left A-V valve replacement	1
VSD closure + PA valved conduit + right A-V valve replacement	1
Total	18

A-V = atrioventricular; PA = pulmonary artery; VSD = ventricular septal defect.

TABLE II Additional Open Heart Operations Required Subsequently in the Same Patient Population

	n
Residual VSD	2
Left A-V valve replacement	2
Left A-V valve anuloplasty	1
Right A-V valve anuloplasty	1
LV-PA conduit replacement	1
Total	7

LV = left ventricular; other abbreviations as in Table I.

TABLE III Effect of Intracardiac Mapping on Subsequent Development of Complete Heart Block

	A-V Conduction Defects			
Procedures	1°	2°	3°	No Change
No mapping (7 patients)	1	0	3*	3
Mapping (11 patients)	2	0	0	9

* Two cases of permanent atrioventricular (A-V) block and 1 of transient complete A-V block.

Results

Mortality: Four (22%) of the 18 patients died. Two patients died early after reoperation for residual ventricular septal defects. One of these 2 patients had a small systemic (right) ventricle which most likely contributed to the poor outcome. One patient died 3 months after surgery from hepatitis and 1 patient died suddenly, presumably from cardiac arrhythmia. The latter patient was known to have complete heart block, an artificial pacemaker, and recurrent premature ventricular contractions.

Follow-up: Three patients who were clinically well and did not require subsequent repeat open heart surgery had a postsurgical cardiac catheterization. All showed normal systemic saturation, none had an intracardiac right-to-left or left-to-right shunt. All had trivial residual pulmonary stenosis of 10 to 12 mm Hg; all 3 showed good systemic right ventricular function. Systemic ventricular function was also determined during cardiac catheterization in 6 additional patients who required repeat operations for various residual defects. In 5 of these patients the systemic ventricular function was considered good by hemodynamic and angiographic techniques, and in 1 patient with severe tricuspid incompetence systemic ventricular function was considered poor.

Conduction defects: Intraventricular conduction defect with QRS prolongation and secondary ST-T wave changes were often noted immediately after open heart surgery. In the late postoperative period, 10 patients showed an intraventricular conduction defect with QRS prolongation and ST-T wave changes and 2 patients who are doing well show minimal ST-T wave changes without QRS prolongation (Fig. 1).

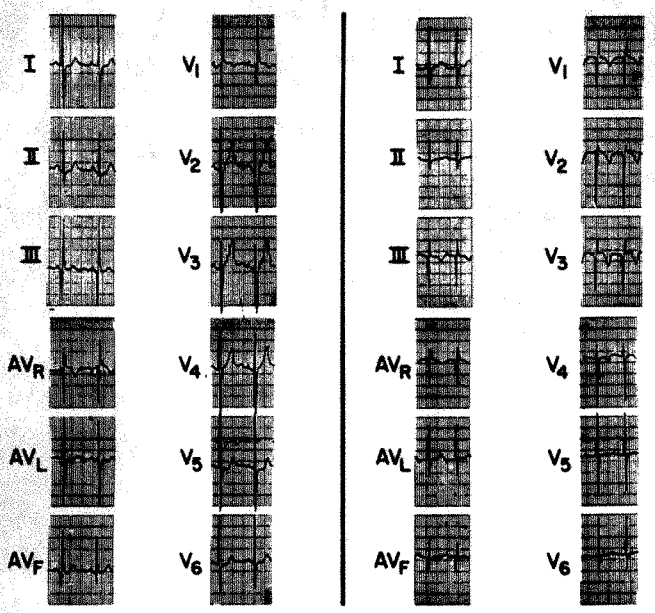

FIGURE 1. Preoperative (**left**) and postoperative (**right**) electrocardiograms in a patient with congenitally corrected transposition of the great arteries who had closure of a ventricular septal defect and insertion of a left ventricular to pulmonary artery conduit. Note that the QRS duration of 0.06 second is similar in the pre- and postoperative tracings in spite of a large left ventriculotomy. The postoperative tracing shows prolongation of the P-R interval to 0.20 second. This patient was 1 of 2 patients who had intraoperative mapping and a residual postoperative A-V conduction disturbance.

Discussion

Indications and results of corrective surgery: Hemodynamically significant cardiac lesions are present in almost all patients with congenitally corrected transposition of the great arteries.[5–10] It is estimated that for such patients the median age of death is 8 years and 3 months and that only 30% of patients get to be 10 years old.[5,10] This sharply curtailed life expectancy and significant morbidity in the form of congestive heart failure or cyanosis in almost all patients with congenitally corrected transposition of the great arteries provide the indication for repair of this uncommon and complex malformation.

In the current series 78% of the 18 patients are alive and well after surgery, with a median follow-up period of 4.5 years. These results suggest that open heart surgery in properly selected patients may be offered with acceptable risk. The prognosis in such patients is related to residual defects, systemic ventricular function, or presence of A-V block. In our patients, when hemodynamic overload or cardiac compromise was detected after surgery it was directly related to identifiable residual defects such as atrioventricular valvular insufficiency, residual ventricular septal defect, or pulmonary conduit stenosis. In the absence of postoperative residual defects it can be expected that longevity and quality of life will improve considerably. Eight of the 18 patients (44%) required a second operation for residual defects. Of these 8 patients, 4 (50%) required additional surgery for repair of either tricuspid (3 patients) or mitral insufficiency (1 patient).

Tricuspid insufficiency before and after surgical correction: Nine of the 18 patients (50%) required surgical treatment of the tricuspid valve during the first or subsequent open heart operation. This high incidence of tricuspid insufficiency noted in our patients is similar to previous angiographic,[7] pathologic,[5,7,11] and surgical observations[1–3] reporting a high incidence of tricuspid malformations in patients with congenitally corrected transposition of the great arteries. Our surgical and follow-up data suggest that the prognosis in patients with congenitally corrected transposition of the great arteries may closely be related to the integrity and function of their tricuspid valve.

It has been suggested[2] that tricuspid insufficiency tends to develop in patients with congenitally corrected transposition of the great arteries after open heart repair once the ventricular balance has been altered by closing the ventricular septal defect. It has been argued[2] that closure of the septal defect will cause the anatomic right ventricle and the tricuspid valve to face systemic pressure without a safety mechanism of tricuspid regurgitation or a ventricular defect. Our experience that 6 of 18 patients required surgical repair of the tricuspid valve during the first operation as well as previous angiographic,[7] pathologic,[5] and surgical[1–3] data indicate that primary and hemodynamically significant A-V regurgitation is common in patients with congenitally corrected transposition of the great arteries whether the ventricular septal defect is repaired or not.

Conduction defects: role of intracardiac mapping: Among our patients none of the 11 who had intracardiac mapping developed permanent complete heart block while minor transient injury to A-V conduction occurred in 2 patients. Of the 7 patients who did not have intracardiac mapping, 2 had permanent complete heart block.

The precise location of A-V conduction in congenitally corrected transposition of the great arteries differs from that in patients with atrioventricular concordance. In almost all patients with congenitally corrected transposition of the great arteries the A-V node is located anteriorly with the His bundle penetrating into the pulmonary ventricle to the right of the pulmonary artery. When a ventricular septal defect is present the His bundle bifurcates along the anterior margin of the ventricular septal defect into the left and right bundle branches. The left bundle branch continues downward along the anterior margin of the ventricular septal defect, and the right bundle branch penetrates the systemic ventricle at the superior margin of the ventricular septal defect or departs from the left bundle somewhere along the anterior margin of the ventricular septal defect. This precise localization and different location of the A-V conduction system was established in recent years by both histologic and electrophysiologic mapping techniques.[12–15]

Most of our patients who did not benefit from intraoperative mapping were operated on before the estab-

lishment of intracardiac mapping and before more recent knowledge of the different location of the conduction system in this cardiac anomaly. In this group of patients the high incidence of permanent complete heart block is similar to previously reported data.[1-3] No patient who had the benefit of intracardiac mapping developed permanent complete heart block. In each of these patients the precise and different location of the A-V conduction system was identified.

The increased knowledge regarding the expected anatomic location made the mapping procedure increasingly brief. With the current knowledge of the precise and different location of A-V conduction in congenitally corrected transposition it is doubtful that electrophysiologic mapping will produce in the future such a substantial difference in the preservation of A-V conduction as seen in our series. However, during the early years when the precise location of A-V conduction was not firmly established this method was definitely helpful in avoiding injury to the A-V conduction system. Our data in these patients indicate that electrophysiologic mapping should be used in any patient in whom the precise location of the conduction system is in doubt.

Intraventricular conduction defect in the form of right bundle branch block pattern is common after open heart surgery for repair of ventricular septal defect or associated pulmonary stenosis, or both.[16,17] This may result from a right ventriculotomy, surgical injury to the right bundle branch, or myocardial damage. Most of our patients showed QRS prolongation and S-T and T-wave changes after surgery. Since poor myocardial function secondary to severe tricuspid insufficiency was detected in only 1 of our patients, it is felt that the postoperative S-T and T-wave changes result most probably from injury to the cardiac conduction system. In patients with congenitally corrected transposition of the great arteries, intraoperative injury to the intraventricular conduction system may conceivably occur during ventriculotomy (when done) or be caused by direct trauma to the right or left bundle branch, or both.[18] Complete injury to the His bundle may be avoided by precise localization of the His bundle and by placing the stitches on the left or on the right septal surfaces away from the conduction system. It has been suggested[18] that in most patients with congenitally corrected transposition of the great arteries the intraventricular conduction defects result from injury to either the left or the right bundle branch, or both, rather than from left ventriculotomy. As observed by Griffiths et al.[19] and by Castagna et al.,[18] left ventriculotomy is usually not associated with significant ventricular conduction delay. This is true whether the left ventricle is in the normal relation[19] or inverted as in congenitally corrected transposition of the great arteries.[18,20]

Optimal age for open heart surgery and preliminary staging operation: Finally, the median age of our patients at the time of open heart repair was 13 years (range 6 to 38). This is a more advanced age compared with other types of elective surgery carried out on most patients with congenital heart disease. The median age of our patients is probably affected by satisfactory palliative operations and surgical experience of early years.

The optimal age for open heart repair is dependent on the underlying associated cardiac defects. In young patients with severe pulmonary obstruction and cyanosis an aortic to pulmonary shunt, usually in the form of a Blalock-Taussig shunt, is advisable. Pulmonary artery banding is advised in very young infants with a ventricular septal defect and pulmonary hypertension without A-V valvular insufficiency.

Elective open heart repair in patients with isolated ventricular septal defect and no pulmonary stenosis should be carried out at age 4 to 6 years. Although pulmonary artery banding is advisable in young infants with pulmonary hypertension, primary ventricular septal defect repair can conceivably be offered to children younger than 4 years of age.

Repair of ventricular septal defect and pulmonary stenosis: In the current patient population, all ventricular septal defects were repaired via a ventriculotomy. However, surgical closure of the ventricular septal defect via a right atrial approach or via the pulmonary artery has been reported.[21,22] Indeed, this approach was used in a patient operated on recently.[23]

Our experience shows that most patients with a ventricular septal defect and pulmonary stenosis require insertion of a pulmonary artery conduit since resection of the subvalvular pulmonary obstruction is limited by the coronary arterial anatomy and by the likelihood of creating atrioventricular block. Patients with congenitally corrected transposition of the great arteries who require insertion of a pulmonary artery conduit should be electively operated on after 6 years of age to allow insertion of an optimal conduit size. Elective surgery should not be postponed beyond adolescence because of secondary myocardial changes associated with ventricular hypertrophy.

Implications: The results and follow-up of our patients suggest that surgical repair of congenitally corrected transposition of the great arteries can be offered with a significantly decreased risk and improved outcome. They also indicate that improved knowledge of the location of the A-V conduction system should result in a marked decrease in the incidence of surgical complete heart block. When postoperative clinical deterioration occurs in such patients it almost always is due to a residual anatomic defect and frequently it is due to an associated congenital malformation of the tricuspid valve rather than to failure of the systemic ventricle. Finally, when QRS prolongation and S-T and T-wave changes occur postoperatively they often reflect intraventricular conduction defects rather than a poor myocardial state.

Acknowledgment

We thank Marie E. Blackman, MD, Henry M. Sondheimer, MD, and Rae-Ellen Kavey, MD for the follow-up data on some of the patients included in this study.

Left and Right Ventricular Adaptation to Right Ventricular Overload Before and After Surgical Repair of Tetralogy of Fallot

PETER E. LANGE, MD, DIETRICH G. W. ONNASCH, PhD, ALEXANDER BERNHARD, MD, and PAUL H. HEINTZEN, MD

On the basis of angiographic projections, left (n = 43) and right (n = 56) ventricular volume data were obtained in patients with tetralogy of Fallot before and after surgical repair. The postoperative patients were divided into 3 groups according to the degree of an additional volume load secondary to a residual ventricular septal defect or pulmonary insufficiency, or both. The decreased left ventricular ejection fraction ($p < 0.01$) in preoperative tetralogy of Fallot in the presence of a normal sized left ventricle suggests depressed global myocardial function, which is not improved after surgical repair, even if excellent results are achieved. A certain functional reserve, however, seems to be preserved, since the ejection fraction did not decrease further with increasing additional volume loads.

Similar enlargement of the right ventricle secondary to comparable degrees of pulmonary insufficiency and residual ventricular septal defect indicates similar effects of additional diastolic and systolic filling on right ventricular function in patients with tetralogy of Fallot after surgical repair. Even in patients with excellent surgical results, such as those without significant right ventricular outflow tract obstruction and additional volume load, right ventricular pump function is depressed, the ejection fraction being significantly ($p < 0.01$) lower than normal. The further decrease of global myocardial function with increasing volume load suggests a loss of functional reserve. Attempts to minimize right ventricular volume load after surgical repair seem advisable.

Only limited and controversial information concerning left and right ventricular performance after surgical repair of tetralogy of Fallot is available.[1–7] For the left ventricle normal[2] as well as decreased[1] ejection fractions were reported in patients after successful surgical repair; in this regard the age at operation may influence the results.[8]

The right ventricle is the chamber primarily involved anatomically. Applying current surgical techniques, an additional volume load to this ventricle postoperatively cannot be prevented in many instances. However, the effect of such a volume load on right ventricular myocardial function has not been assessed precisely. The main reason appears to be the inability to quantitate the degree of myocardial function with acceptable accuracy, which was achieved in the present study with a roentgen videodensitometric method.[9] The purpose of this study therefore was to determine and compare the effect of different degrees of volume load on left and right ventricular myocardial function in patients with tetralogy of Fallot after surgical repair.

From the Department of Pediatric Cardiology and Bioengineering and the Department of Cardiovascular Surgery, University of Kiel, West Germany. This study was supported by Grant He769-1 from the Deutsche Forschungsgemeinschaft and by Grant 202a from the Bundesministerium für Forschung und Technologie, Bonn, West Germany. Manuscript received July 8, 1981; revised manuscript received February 17, 1982, accepted March 5, 1982.

Methods

Patient Groups (Tables I and II)

Preoperative group: Tetralogy of Fallot was defined as a combination of a large ventricular septal defect with an "overriding" aorta, allowing equalization of the pressure in the 2 ventricles, and severe right ventricular outflow obstruction, causing a bidirectional interventricular shunt with a net right-to-left shunt. Although some of the patients had a patent foramen ovale, none had evidence of interatrial shunting on oximetry or cineangiography.

Eighteen preoperative patients were studied. Three of them had a poorly functioning aortopulmonary shunt (1 Blalock-Taussig in the left ventricular group and 2 Waterston-Cooley in the right ventricular group). The ventricular volumes in these children were not larger than the mean of the respective group.

Postoperative group: Included in the postoperative group of 38 patients were those without significant residual defects (no ventricular septal defect and a maximal systolic gradient between right ventricle and pulmonary artery of 30 mm Hg or less) and those with an increased quantified preload caused by a ventricular septal defect or pulmonary insufficiency, or both. All patients had right bundle branch block.

Aortopulmonary shunts were closed at surgical repair in 5 patients in the left ventricular study group (1 Blalock-Taussig in those with a volume load less than 20%; 1 Blalock-Taussig and 3 Waterston-Cooley in those with a volume load greater than 50%) and 6 patients in the right ventricular study group (1 Blalock-Taussig in those with a volume load less than 20%; 2 Blalock-Taussig in those with a volume load of 20 to 50%; 1 Blalock-Taussig and 2 Waterston-Cooley in those of a volume load greater than 50%). Infundibulectomy and closure of the ventricular septal defect with a patch as well as commissurotomy or insertion of a transanular patch, or both, were performed in all patients. A transanular patch was utilized in 18 patients in the left ventricular study group (9 transanular patches with 2 monocusps in those with a volume load less than 20%; 6 transanular patches with 2 monocusps in those with a volume load of 20 to 50%; 3 transanular patches without monocusps in those with a volume load greater than 50%) and 25 patients in the right ventricular study group (3 transanular patches without monocusps in the group with a volume load less than 20%; 10 transanular patches with 2 monocusps in those with a volume load of 20 to 50%; 12 transanular patches with 5 monocusps in those with a volume load greater than 50%).

Angiograms: Included for study were only those patients whose angiocardiograms were of high quality, allowing a distinct border definition of the selected beat. Of the available angiocardiograms, 48% of the left ventricular angiograms and 47% of the right ventricular angiograms in the preoperative group and 70 and 58%, respectively, in the postoperative group could be analyzed. Patient age, height, weight, and body surface area for the included pre- and postoperative patients at the time heart catheterization was performed are summarized in Tables I and II. For the time from operation to restudy see Figures 7 and 8.

Study period: The study included patients studied from February 1975 to February 1980. Premedication, catheterization procedure, and quantitative analysis of routine angiocardiograms were the same during this period. Corrective surgery was performed between February 1975 and February 1979. All patients were operated on under moderate hypothermia (25 to 30°C), and hemodilution to a hematocrit of 30%. Cardioplegia has been used since 1978 in 10 patients; 7 of these children were included in the left ventricular study group (volume load less than 20%, n = 4; 20 to 50%, n = 2; greater than 50%, n = 1) and 9 in the right ventricular study group (volume load less than 20%, n = 1; 20 to 50%, n = 2; greater than 50%, n = 6).

Data Acquisition

Cardiac catheterization: The patients were studied in the fasting state in the supine position. Infants up to 12 months of age received Luminal® (acidum phenylbarbituricum) (10 mg/kg), and older children Dolantin® (pethidine) (1 to 1.5 mg/kg), Luminal® (10 mg/kg), and atropin (0.01 to 0.015 mg/kg) premedication, given 1 hour before the diagnostic cardiac catheterization.

Before the first cineangiocardiogram was taken, the shunts were quantified by oximetry. Left and right ventricular pressure was recorded using a side hole catheter (NIH 6F or 7F) connected to a Statham P23db transducer (Statham Instruments, Oxnard, California). Zero pressure was referenced to the level of the venae cavae in the lateral projection.

Angiocardiography: ventricular volumes: Volumes of the left and right ventricles were obtained on the basis of biplane videoangiocardiographic projections (anteroposterior and lateral), recorded side by side at 50 frames/s on magnetic tape together with physiologic reference data such as electrocardiogram and pressure after selective injection of 76% Urografin® (Schering AG, Berlin) into the left (1 ml/kg of body weight) or right ventricle (1.5 ml/kg of body weight). For calibration purposes a steel sphere of known diameter was filmed at the location the ventricles occupied. The borders of the biplane projections (steel sphere and ventricles in sinus beats) and "anatomic landmarks" [10] were marked with an x/y coder. Volumes at end-diastole and end-systole were calculated for the left and right ventricles with area-length and multiple slices methods, respectively.[11] All values were corrected with factors appropriate for spatial position and cardiac phase.[12,13]

The following variables for the left and right ventricle were calculated from end-diastolic and end-systolic volumes and compared with normal values, reported before[12,13]: stroke volume (end-diastolic − end-systolic volume), ejection fraction (stroke volume/end-diastolic volume), and systolic output (stroke volume × heart rate).

End-diastolic, end-systolic, and stroke volumes were normalized for the corresponding body surface area to the power of 1.219, since we found a nonlinear relationship with an exponent of e = 1.219 between volume variables and body surface area.[12,13] The stroke output index equals stroke output divided by body surface area. Detailed descriptions of the videometric system were reported previously.[10,14]

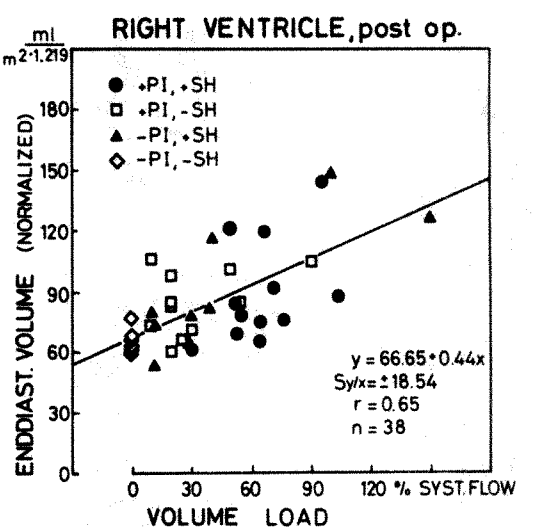

FIGURE 1. Right ventricular end-diastolic (END DIAST.) volumes (normalized for body surface area to the power of 1.219) of patients with tetralogy of Fallot after surgical repair (postop.) as a function of an additional volume load (expressed as percent systemic [SYST.] flow) secondary to pulmonary insufficiency (+PI) or residual ventricular septal defect (+SH), or both. −PI = no PI; −SH = no residual shunt.

BSA = body surface area; ECC = time of extracorporeal circulation; EDP = end-diastolic pressure; EDV, ESV, SV = end-diastolic, end-systolic and stroke volume, respectively, each normalized for BSA to the power of 1.219; EF = ejection fraction; GRAD = maximal systolic gradient between right ventricle and pulmonary artery; HR = heart rate during angiography; ISCH = time of ischemic arrest; Max = maximum; Min = minimum;

Quantification of pulmonary insufficiency: The degree of pulmonary insufficiency was quantified by roentgen densitometry, a method described before.[9,15] Basically it is a dye dilution technique. After the injection of 5 to 8 ml of contrast medium (Urografin 76%) into the right ventricle, the total amount of this indicator was measured by means of an electronic sampling window covering the entire silhouette of the right ventricle in the lateral x-ray plane stored on magnetic tape. The ratio of changes in amplitudes of the resulting densitogram represents the reflux of dye (deflections at the time of end-diastole minus preceding end-systole) to the amplitude caused by the forward flow (difference of deflections between end-diastole and the following end-systole). It allows the calculation of the regurgitant fraction, that is, the ratio of regurgitant volume over total stroke volume. The excellent accuracy of this method was demonstrated experimentally in comparison with electromagnetic measurements,[16] the standard deviation being 6.5%.

Determination of right ventricular volume load: Comparable degrees of pulmonary insufficiency and residual ventricular septal defect caused a comparable degree of additional volume load on the right ventricle, as judged by the end-diastolic volume (Fig. 1). Therefore it appeared justified to group together patients with pulmonary insufficiency (PI) and those with ventricular septal defect, or both, when considering the effects of volume load on the right ventricle o postoperative patients. Total volume load (VL) was calculatec according to the formula VL = (PI + SH)/(100 − PI) and ex pressed as percent of the systemic flow (SH = left-to-righ shunt across a residual ventricular septal defect).

To compare 2 groups of data the *t* test was used, appro priate for either equal or different variances of the mean.

Results

The results are shown in Tables I and II and Figure 2 to 5. The previously reported normal values[12,13] (95% confidence limits of the mean) are included for comparison.

Before surgical correction: In the 18 preoperative patients mean end-diastolic, end-systolic, and stroke volumes, as well as ejection fraction of the right ventricle were not significantly different from normal while the stroke volume output index was significantly reduced (Fig. 2 and 3). For the left ventricle (17 patients), end diastolic volumes were at the lower limit of the norma range (Fig. 4). Stroke volume, systolic output index, and ejection fraction were significantly lower than norma (Fig. 5). There was no correlation between these volume

= number of patients in each group; NS = not significant ($p > 0.05$); Pmax = maximal systolic pressure; SD = standard deviation; Sign = statistically significant at given p level compared with normal; SOI = systolic output index; VL = total volume load related to the systemic flow.

variables and tetralogy of Fallot, as judged by the hematocrit (Fig. 6). Peak systolic and end-diastolic pressures were equal in both ventricles.

After surgical correction: After surgical repair in 26 patients end-diastolic and stroke volume of the left ventricle were significantly increased in all 3 volume load groups in comparison with normal values (Fig. 4). Up to a volume load of 20 to 50%, stroke volume and systolic output index of the left ventricle were normal and significantly ($p < 0.01$) increased compared with the preoperative state (Fig. 5). At a volume load of greater than 50%, these variables were significantly greater than normal (Fig. 5). The left ventricular ejection fraction remained significantly reduced postoperatively, but did not decrease further with increasing volume load (Fig. 5). There was a correlation of $r = -0.611$ between left ventricular ejection fraction and patient age at operation (Fig. 7) and $r = -0.407$ between ejection fraction and the time after surgical repair (Fig. 8).

For the right ventricle after surgical repair, end-diastolic, end-systolic, and stroke volumes as well as stroke output index increased with increasing volume load (Fig. 2 and 3). Since end-systolic volume increased progressively more than end-diastolic volume, the resulting ejection fraction decreased with increasing volume load (Fig. 3), being 0.513 ± 0.065 at a volume load of greater than 50%. There was no correlation between right ventricular ejection fraction and the age at operation ($r = 0.150$) or time after surgical repair ($r = -0.0005$) (Fig. 8).

Discussion

The left ventricle before surgical correction: Left ventricular stroke output is a close approximation of but not equal to pulmonary flow in preoperative tetralogy of Fallot with a bidirectional shunt. Nevertheless, the significantly ($p < 0.01$) reduced left ventricular stroke output index (Fig. 5), which has also been observed by others,[1,17] is an expression of diminished pulmonary flow, since the net shunt is right-to-left. On the basis of anatomic studies, end-diastolic volume was found to have a tendency to be smaller than normal,[17,18] which is in agreement with our data (Fig. 4). A significant reduction of angiocardiographically estimated end-diastolic volume was found only by Jarmakani et al.[1,19] in conjunction with a hemoglobin greater than 16 g/100 ml.

Abbreviations as in Table I.

These children may have had a severe form of tetralogy of Fallot.

The significantly reduced left ventricular ejection fraction indicates impaired myocardial function, especially since impedance to ejection in patients with a large interventricular communication is less than normal.[1] It confirms the findings of Jarmakani et al.[1,19] and may be related to histologic alterations, which have been observed in the left ventricular myocardium of patients with tetralogy of Fallot.[20]

The right ventricle before surgical correction: The low stroke output index (Fig. 3) in the presence of a normal end-diastolic volume (Fig. 2) has been related to a right-to-left shunt at the ventricular level.[19] The slightly but not significantly reduced ejection fraction (Fig. 3) indicates that in this group of patients with a mean age of less than 3 years global right ventricular myocardial function is not depressed although systemic pressures are generated at a reduced arterial oxygen saturation.

The left ventricle after surgical correction: Information concerning left ventricular function after surgical repair of tetralogy of Fallot is limited and conflicting. Normal angiographic end-diastolic volume and ejection fraction were noted in children who were operated on successfully without residual defect before the age of 2 years[2] as well as later.[4] By contrast, Jarmakani et al.[1] observed that end-diastolic volume was slightly but significantly increased and that ejection fraction was significantly decreased. Our results are in agreement with the latter findings. Without a significant residual defect, stroke volume and systolic output index became normal (Fig. 5) and pulmonary flow equaled systemic flow. The left ventricle adapted to this increased preload with increased end-diastolic and end-systolic volumes. Both mean values were significantly greater than the preoperative as well as the normal ones (Fig. 4). Since the ejection fraction remained significantly diminished, this finding indicates reduced global left ventricular myocardial function despite normal systemic oxygen saturation and lack of residual defects.

Diffuse and focal myocardial fibrosis observed in preoperative patients of various ages[20] could be the anatomic substrate for the reduced ventricular myocardial function. The rather poor correlation ($r = -0.611$) between left ventricular ejection fraction and age at surgical repair (Fig. 7) does not necessarily sup-

port the suggestion[8] that early operation improves left ventricular myocardial function. A decreasing ejection fraction with age as part of the natural history of this disease may be a contributing factor. Whether further deterioration occurs after surgical repair, particularly in relation to age at operation or residual defects (especially a residual ventricular septal defect), cannot be answered by this study. The low correlation ($r = -0.407$) between left ventricular ejection fraction and time after surgical repair (Fig. 8) does not justify such a conclusion. An increasing volume load resulted in increasing end-diastolic and end-systolic volumes as well as stroke volume output index. The ejection fraction, however, did not decrease further, which suggests that a certain functional reserve is preserved.

The right ventricle after surgical correction: In the group of patients with minimal or no residual defects after operative repair, stroke volume, stroke output index, and ejection fraction were significantly reduced. In the presence of normal end-diastolic and end-systolic volumes this indicates a depressed right ventricular function even in those patients in whom an excellent surgical result could be achieved. These findings are in agreement with those of Burnell et al.[5] and Jarmakani et al.,[6] but differ from those of Graham et al.,[7] who found a normal ejection fraction in similar patients. The age at operation may be an important factor, since increasing myocardial fibrosis has been observed with increasing age in patients with tetralogy of Fallot.[20] The mean age at operation of our patients (5.5 years) is comparable to that of those reported by Graham et al.[7] (4.1 years), while that of the children studied by Burnell et al.[5] was less than 4 years. The latter, however, were operated on during the late 1960s. Further investigations are needed.

Clinical role of postoperative right ventricular volume load: One of the common sequela of surgical repair is a volume load due to a residual ventricular septal defect or pulmonary insufficiency, or both.[21–27] The difficulty in quantifying the degree of pulmonary insufficiency[28] has undoubtedly contributed to the lack of information on the effects of pulmonary insufficiency on the myocardial function of the right ventricle after surgical repair. We determined pulmonary insufficiency with a videodensitometric method[9] in all patients undergoing routine postoperative heart catheterization. The accuracy of this technique has been documented in animal experiments by comparison with electro-

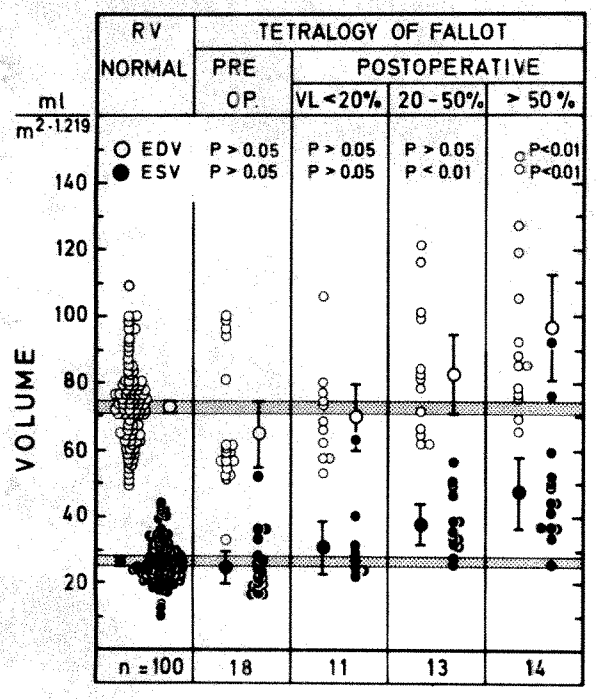

FIGURE 2. Right ventricular (RV) end-diastolic (EDV) and end-systolic (ESV) volumes (normalized for body surface area to the power of 1.219) of pre- and postoperative patients with mean values and 95% confidence limits (**brackets**). The postoperative patients are divided into 3 groups according to an additional right ventricular volume load (VL, expressed as percent of systemic flow) secondary to pulmonary insufficiency or residual ventricular septal defect, or both. Differences with normal data (**shaded areas**) are depicted as p values.

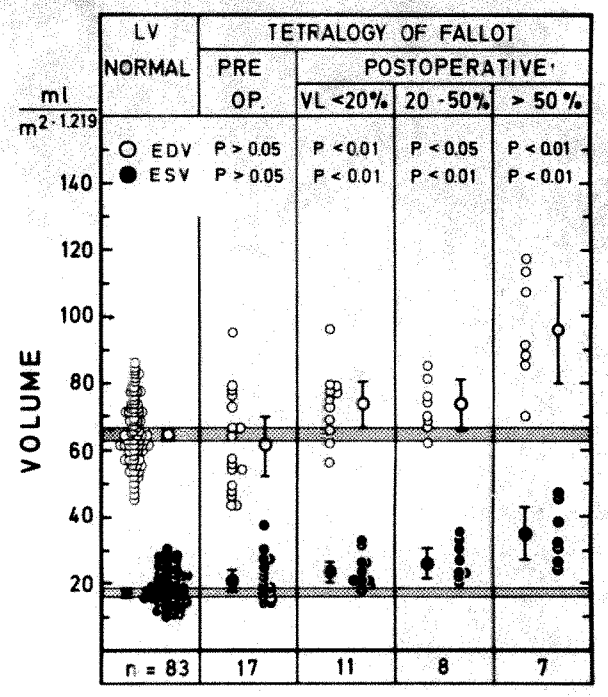

FIGURE 4. Left ventricular (LV) end-diastolic (EDV) and end-systolic (ESV) volumes (normalized for body surface area to the power of 1.219) of pre- (PRE OP) and postoperative patients with mean values and 95% confidence limits. The postoperative patients are divided into 3 groups according to an additional left ventricular volume load (VL, expressed as percent of systemic flow) secondary to a residual ventricular septal defect. Differences with normal data (**shaded**) are depicted as p values.

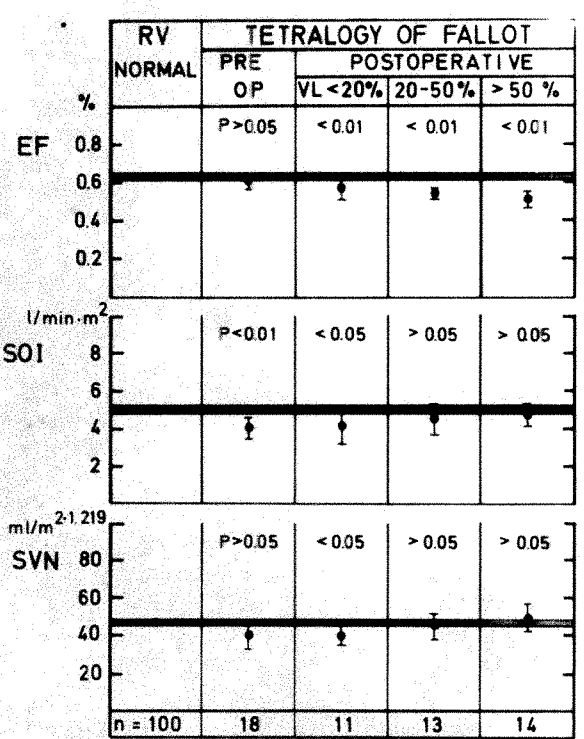

FIGURE 3. Mean values and 95% confidence limits of right ventricular (RV) ejection fraction (EF), systolic output index (SOI), and normalized stroke volume (SVN) of pre- (PRE OP) and postoperative patients. The postoperative patients are divided into 3 groups as in Figure 2.

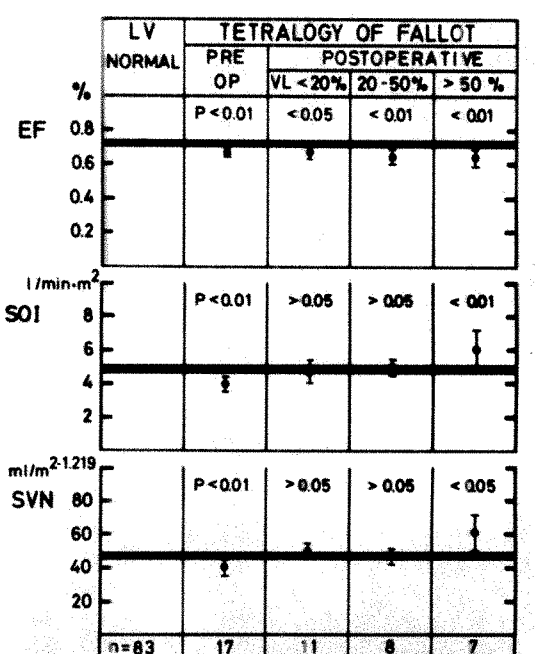

FIGURE 5. Mean values with 95% confidence limits of left ventricular (LV) ejection fraction (EF), systolic output index (SOI), and normalized stroke volume (SVN) of pre- (PRE OP) and postoperative patients. The postoperative patients are divided into 3 groups according to an additional volume load (VL) as in Figure 4.

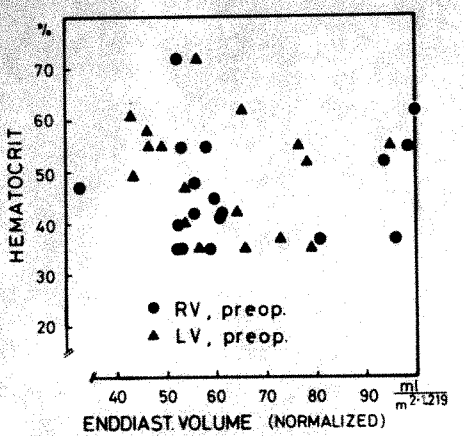

FIGURE 6. Right (RV) and left (LV) ventricular end-diastolic (END DIAST.) volumes (normalized for body surface area to the power of 1.219) of preoperative (PRE OP) patients with tetralogy of Fallot as a function of the hematocrit. There is no correlation.

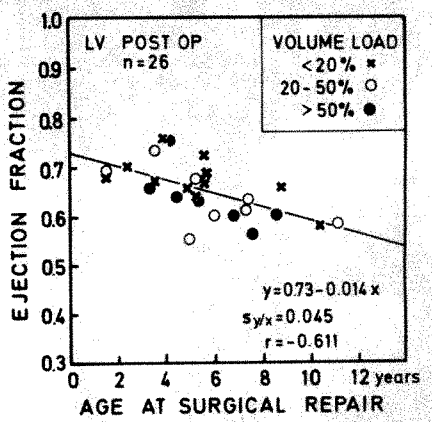

FIGURE 7. Relationships between postoperative (POST OP) left ventricular (LV) ejection fraction and the age at surgical repair. The patients are divided into 3 groups according to an additional volume load (expressed as percent of systemic flow) secondary to a residual ventricular septal defect.

magnetic flow values.[16] Our results in this study were expressed in terms of percent of the systemic flow, thus allowing comparison with the flow across a residual ventricular septal defect.

Similar degrees of additional right ventricular filling in diastole and systole resulted in a similar degree of right ventricular enlargement (Fig. 1). A right ventricle dilated as a result of a ventricular septal defect is not surprising. Graham et al.[29] reported a marked increase in right ventricular end-diastolic size in patients with an isolated ventricular septal defect.

Although the number of patients found to have isolated pulmonary insufficiency or residual ventricular septal defect is small, it seemed justified to assume a similar effect of each lesion on diastolic and systolic volume load. With increasing volume load, end-diastolic and end-systolic volumes increased while ejection fraction decreased. In conjunction with increased end-diastolic pressure this indicates a loss of functional reserve. It is probably related to fibrotic changes secondary to preoperative hemodynamic function,[20] the loss of myocardium by ventriculotomy and infundibulectomy, the presence of a noncontractile patch, and volume overload. The relative contributions of these factors to the functional abnormalities remain difficult to determine. Our data, gained under comparable diagnostic and surgical conditions, suggest, however, that a postoperative volume load on the right ventricle is a decisive factor. It is supported by the studies of Wessel et al.,[30] who showed on the basis of serial exercise testing in mildly symptomatic and asymptomatic patients after surgical repair that isolated pulmonary insufficiency is less well tolerated than isolated residual obstruction. Thus, one must attempt to avoid or minimize postoperative pulmonary insufficiency. This may in part be achieved by a less liberal use of transanular patches. To optimize the size of a necessary transanular patch further quantitative studies are needed, and such studies are underway in our department.

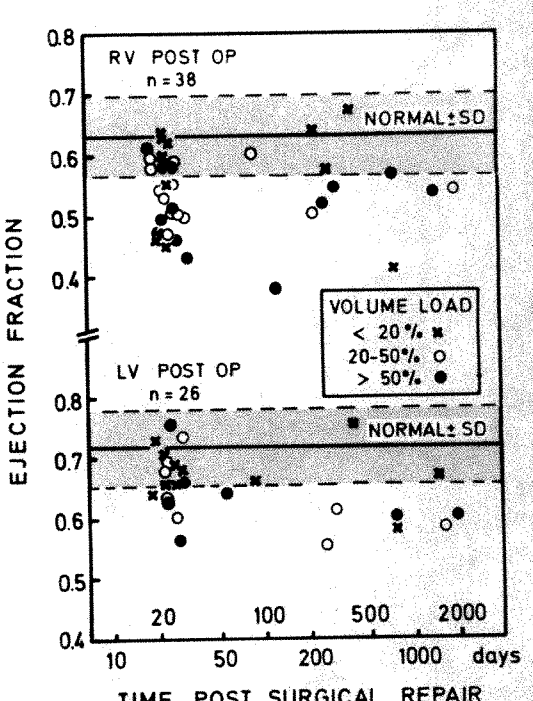

FIGURE 8. Relationship between postoperative (POST OP) ejection fraction and time after surgical repair (logarithmic scale) for the right (RV) and left (LV) ventricle. The patients are divided into 3 groups according to an additional volume load expressed as percent of systemic flow. For the right ventricle there is no ($r = -0.0005$) and for the left ventricle a slight ($r = -0.407$) correlation. SD = standard deviation.

Currently available antianginal agents...
and how they are most appropriately employed as

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

›psis of the Symposium

l: Nitrates

nitrates both reduce myocar-
xygen demand and increase
ardial oxygen supply, their use
ranted as initial therapy for the
›l of angina pectoris. Dosage
often vary significantly from
ıt to patient, and attention
d be given to ensure that an
ıate dosage level has been
lished.

2: Nitrates and blockers

ngina refractory to maximum-
nitrate therapy, the comple-
ary actions of beta blockers
ıitrates provide a rational ther-
ic modality. At this point a beta
er should be added to the
e regimen.

3: Nitrates and ıum antagonists

ım antagonists have special
ılness in controlling cases
e the myocardial oxygen sup-
diminished by coronary vaso-
m; their use in combination
nitrates is recommended if
2 therapy is unsatisfactory (or if
›atient has variant or vasospas-
ıgina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

The basic antianginal agent in these basic dosage forms

ISORDIL® SUBLINGUAL
Sublingual Tablets, 2.5 mg, 5 mg, and 10 mg

ISORDIL® CHEWABLE
Chewable Tablets, 10 mg

ISORDIL® TITRADOSE®†
Oral Tablets with E.Z. Split® scoring: 5 mg, 10 mg, 20 mg, and 30 mg

ISORDIL® TEMBIDS® Capsules
Sustained-Release Capsules, 40 mg

In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

®
ıves Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE)
IS BASIC

*Indications: Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

Critical Pattern Recognition.™ The next wave in Holter data analysis.

DEL MAR AVIONICS

No two patients have exactly the same ECG waveforms.

So to give you the most precise data analyzer for processing Holter tapes, we offer Critical Pattern Recognition.

Both the Trendsetter™ and Evaluator™ Data Analysis Systems are computer-controlled to recognize normal and variant ECG waveforms for each individual patient.

Waveforms are categorized, counted and compared to the patient's typical ECG, even though these normal patterns may vary throughout the monitoring period.

Moreover, analysis is halted automatically upon occurence of significant ectopic patterns, such as paired VEs/SVEs, R-on-T, V-Tach, SV-Tach, Ventricular Bigeminy, Bradycardia beats/runs and other critical events.

Dual 12-in CRT displays provide unsurpassed control of real-time data. And a wide selection of report formats (alphanumerics, graphics and analog trends) provide comprehensive permanent data for improved patient management.

Additionally, the Trendsetter can be updated to accommodate blood pressure, pacemaker analysis, dual floppy disks and other options. Choose only what you need now and add more capability later.

For more details on the first Holter data analysis systems to offer Critical Pattern Recognition, call or write: Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

Trendsetter and Evaluator are trademarks, Del Mar Avionics.

INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Prof. Clinical Medicine, Columbia Univ. College Physicians and Surgeons, Director R.A. Cooke Institute of Allergy, St. Luke's-Roosevelt Hosp., N.Y.

Text by 47 specialists, 1,035 pages, 147 illus., 78 full-color photos. Completely indexed. $79.95.

In 36 revealing chapters are reviewed the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation. INFECTIONS IN THE ABNORMAL HOST will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

[1] "With this comprehensive work, Grieco has clearly filled a marked gap in the infectious disease literature. Various sections should be of interest to a broad range of practitioners . . . should serve as an important starting point and a useful reference source for any physician concerned with the complicated but increasingly important patient, the compromised host."
Philip A. Pizzo, MD, National Cancer Institute, **NEW ENGLAND JOURNAL OF MEDICINE**, Jan. 8, 1981

"This work will serve the physician well in caring for patients with serious infections. It is well organized and easy to use for quick reference. It also serves as an extensive review of infections in the defective host for specialists in infectious disease, pulmonary medicine, and cancer."
W. Lee Fanning, MD, **JOURNAL AMERICAN MEDICAL ASSOCIATION**, Jan. 2, 1981

"This important text should play a valuable role in the understanding and management of infections in the abnormal host and shows how clinical microbiologists, immunologists, and infectious disease clinicians can work together in the diagnosis and management of patients."
D.M. Weir, Dept. Bacteriology, Univ. of Edinburgh, **LANCET**, July 19, 1980

[2] "This book is expertly edited . . . an outstanding feature is the thoroughness in which the book is indexed . . . As a comprehensive text for the academician and as a sound guide for the clinician in every field, the book is highly recommended. Immunologists, microbiologists, oncologists, internists, and specialists in infectious diseases should either purchase the book or have a copy readily available as a reference. Medical and graduate school libraries should own copies."
E.A. Gorzynski, **IMMUNOLOGICAL COMMUNICATIONS**, Sept. 7, 1980

[3] "And so we must not only choose the correct antibiotic but also overcome the infection in this compromised, immunosuppressed patient or what we commonly term the person with poor resistance. This clearly calls for a book of guidance and this is it, all 1,035 pages of it, beautifully edited, lavishly produced, and with the experience and wisdom of 47 contributors."
D. Geraint James, FRCP, Dean Royal Northern Hospital, London, **MILAN DAILY MEDICAL NEWSPAPER**, May 1980

AJCJ2

The ECG cartridge with 50 lives.

Special offer at AHA Exhibit, Booth H-22

DEL MAR AVIONICS

Conventional 24-hour Holter reel tapes have less than 9 lives. And cassettes are recommended only for single use.

But our advanced design, four-channel cartridge, when used with the Series 449 Electrocardiocorder® Systems, may be erased and re-used for up to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically designed with extended tape life in mind. Combining the convenience of a cassette with the accuracy of a reel-to-reel design, the cartridge tape can be manipulated at today's high scanning speeds with exact precision. Moreover, precise data management can be attained without tape stretching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.

And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

*Test data available upon request.

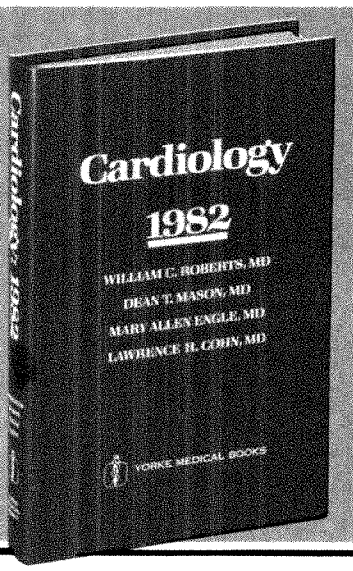
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, New York 11205 AJCJ2

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)

(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

DEL MAR AVIONICS

For more than 20 years, we've provided cardiologists with the most advanced Holter monitoring data analysis systems in the world.

Now we're extending that experience to ultrasound imaging by offering the Model 8000 Sector Imager™ Echocardiography System.

Priced under $50,000, this complete echocardiography system provides optimum performance from your capital equipment budget.

For example, you get high-resolution, digitally enhanced images. Simultaneous 2-D and M-Mode displays. Variable sector angles of 30, 60, or 90 degrees to increase clinical versatility, as well as A-Mode display with Time Gain Compensation. Plus many more features.

The Sector Imager System is also simple to use. Logically arranged controls enhance operator efficiency. Large diameter wheels provide easy mobility throughout the hospital, office or clinic. And a unique transducer design permits easy access to all acoustical windows.

Data management is further extended by a multi-speed fiber optic recorder and built-in VTR which adds post processing capability in either sector or rectilinear formats.

Most importantly, our Sector Imager System is supported by more than 35 service offices nationwide. So the same factory-trained specialists who support your Holter data analysis equipment can now service your echocardiography systems as well.

For more details on the echocardiography system that's surprisingly affordable, request Bulletin 8000 from Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714. Telephone 714/549-1500 Telex 68-5621.

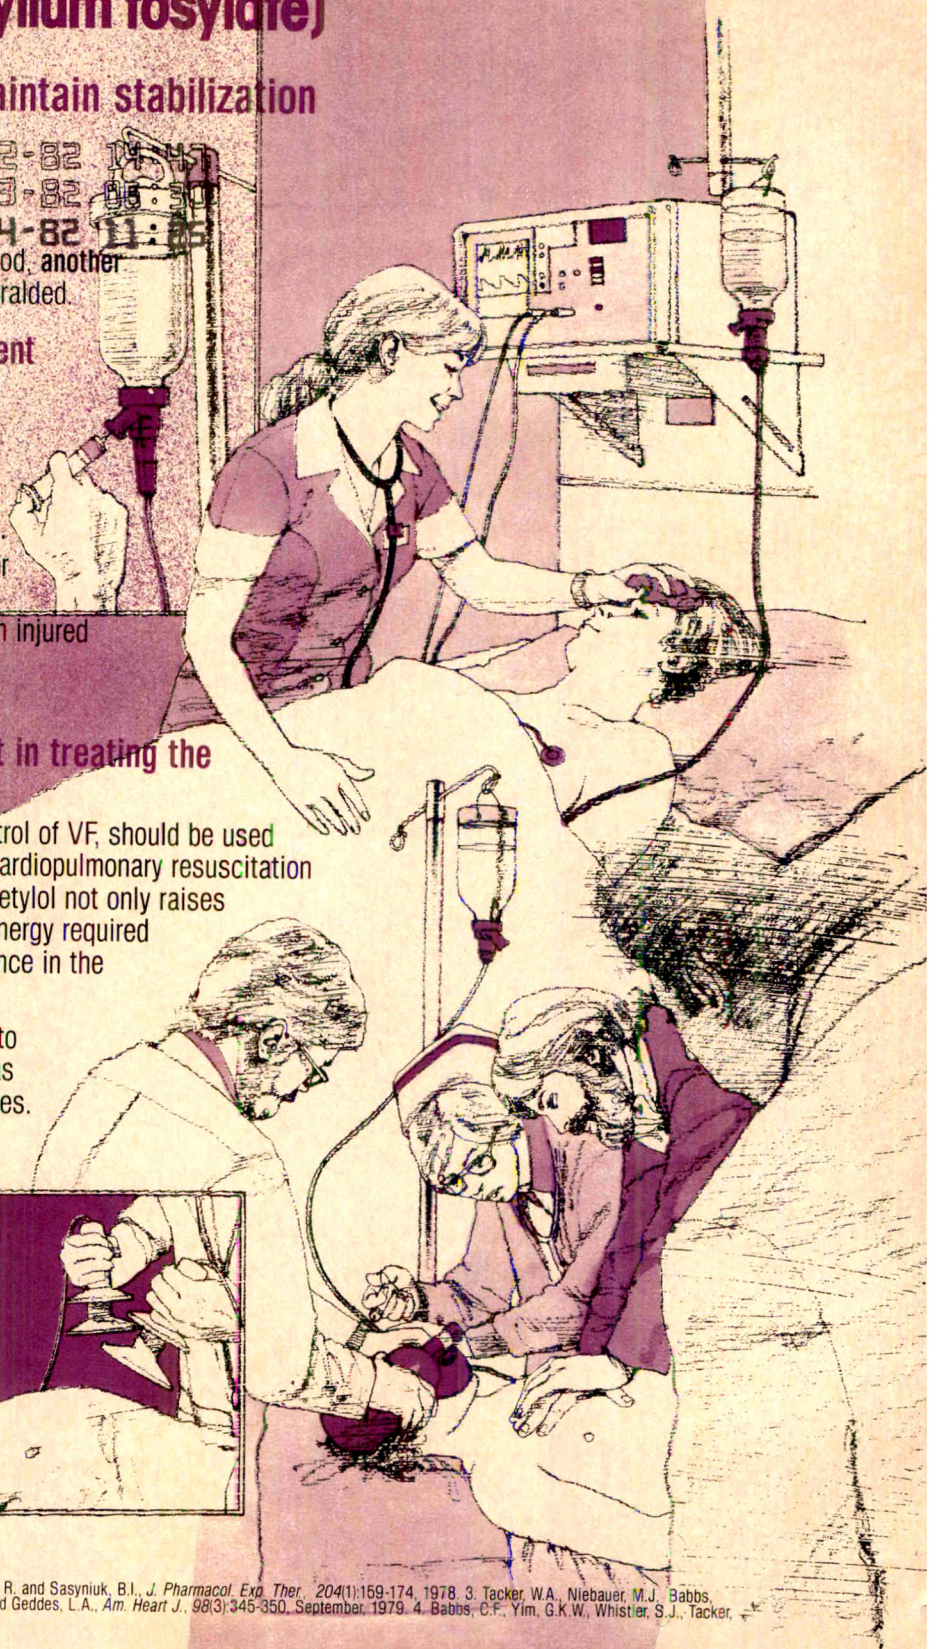
In the CCU, after conversion of VF...

Bretylol® (bretylium tosylate)

Follow-up therapy helps maintain stabilization

During the two or three days **after** conversion of ventricular fibrillation, the patient may still be electrically unstable. During this critical high risk period, **another** episode of VF may occur, completely unheralded.



Good reasons to keep the VF patient on Bretylol follow-up therapy!

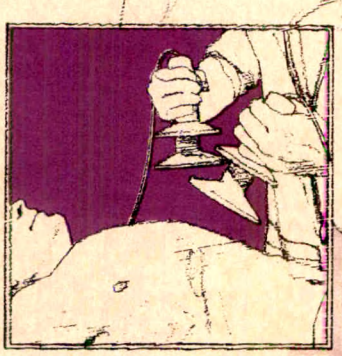
1. Bretylol raises the VF threshold almost three times control, protecting the heart from fibrillation.[1]*
   No other agent has this dramatic effect.
2. Bretylol also suppresses reentry, a major cause of VF by helping to equalize the electrophysiological differences between injured and normal ventricular tissue.[2]*
   No other agent can do this.

And, Bretylol offers added benefit in treating the acute episode, too.

Bretylol, a first-line agent in the acute control of VF, should be used in the very first stages of VF, as soon as cardiopulmonary resuscitation and countershock have been attempted. Bretylol not only raises the fibrillation threshold...it reduces the energy required for defibrillation.[3,4]* Another critical difference in the Bretylol mechanism of action.

That's why it makes sense to use Bretylol to maintain stabilization in the CCU, as well as in the first few minutes of acute VF episodes.

There are no contraindications to the use of Bretylol in VF. Hypotension and postural hypotension have been the most frequently reported adverse reactions. Consult brief summary of prescribing information on the following page.



For further information, please contact the Medical Services Department, American Critical Care, a division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

Bretylol...adds a different and unique dimension in control of ventricular fibrillation

American Critical Care

Bretylol®
(bretylium tosylate)

Brief summary of prescribing information

INDICATIONS — BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS — There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS — 1. Hypotension: Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY — The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN — The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS — 1. Dilution for Intravenous Use: BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use of Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

ADVERSE REACTIONS — Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED — NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP, pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

They only taste the water.

In potassium therapy
patient compliance is not the only advantage with KAON CL-10... it provides all the benefits of 8 mEq wax-matrix tablets for patients who can't or won't take liquid supplements... PLUS simplified dosage.

10 mEq strength permits fewer tablets, fewer doses per day.

10 mEq strength provides 25% more KCl with no increase in cost.

10 mEq strength encourages compliance because of a more convenient dosage schedule.

10 mEq KCl strength is more easily adjusted to multiples of 10.

It's time for a change to

KAON CL™-10

(potassium chloride)
10mEq controlled release tablets

ADRIA LABORATORIES INC., Columbus, Ohio 43215
Please turn page for brief summary of prescribing information.

A121

KAON CL™-10 (potassium chloride) 10 mEq Controlled Release Tablets

Description: Kaon Cl™-10 mEq is a sugar coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon Cl™-10 mEq (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon Cl-10 mEq should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:
1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100 and 500; Stat-Pak® (Unit-Dose) box of 100.

Early Assessment of Hemodynamic Status After Repair of Tetralogy of Fallot: A Comparison of 24 Hour (Intensive Care Unit) and 1 Year Postoperative Data in 98 Patients

PETER LANG, MD, CARL W. CHIPMAN, RN, HAROLD SIDEN, ROBERTA G. WILLIAMS, MD, WILLIAM I. NORWOOD, MD, and ALDO R. CASTANEDA, MD

Hemodynamic data obtained in the intensive care unit, immediately after repair of tetralogy of Fallot, were compared with measurements obtained at 1 year postoperative catheterization in 98 infants and children. Eight of 12 patients who had pulmonary artery oxygen saturation of 80% or greater in the intensive care unit had a pulmonary to systemic flow ratio greater than 1.5 at catheterization; all 79 patients who had a pulmonary artery oxygen saturation of less than 80% in the intensive care unit had a pulmonary to systemic flow ratio of 1.5 or less at catheterization. Five of six patients who had a right ventricular outflow tract pressure gradient greater than 40 mm Hg in the intensive care unit had a gradient greater than 40 mm Hg at catheterization; 7 of 61 patients who had a right ventricular outflow tract gradient of 40 mm Hg or less in the intensive care unit had a gradient greater than 40 mm Hg at catheterization. The addition of measurements of right ventricular pressure and the right ventricular to systemic arterial pressure ratio in the intensive care unit did not improve sensitivity in identifying patients with a right ventricular outflow tract gradient greater than 40 mm Hg at catheterization.

Intensive care unit measurement of pulmonary artery oxygen saturation is valuable for determining the presence or absence of a significant left to right shunt after repair of tetralogy of Fallot and should be considered an adjunct to patient management. Intensive care unit measurement of the right ventricular outflow tract gradient identifies patients with a significant right ventricular outflow tract gradient at catheterization but is not highly sensitive.

The results of the present surgical treatment of tetralogy of Fallot have progressed to a point where operative mortality and morbidity are exceedingly low[1,2]; present concerns focus on the timing of surgery,[3–5] variations in surgical technique,[6] and late hemodynamic results.[7,8] Patients who remain symptomatic after surgery often have identifiable persistent structural abnormalities.[9] It has been demonstrated that myocardial performance will be adversely affected by such defects.[10] The purpose of the present investigation was to determine whether patients with residual defects can be identified in the immediate postoperative period so that appropriate treatment can be undertaken without delay. Accordingly, hemodynamic data obtained in the early (24 hour) postoperative period are compared with those obtained 1 year after surgery.

Postoperative assessment of hemodynamic status after repair of tetralogy of Fallot has been routine at this medical center since 1974. Catheters are placed in the left atrium, right atrium, pulmonary artery (through the right ventricular free wall), and a peripheral systemic artery at the time of surgery. Simultaneous determination of the oxygen saturation of blood samples obtained through these catheters allows determination of

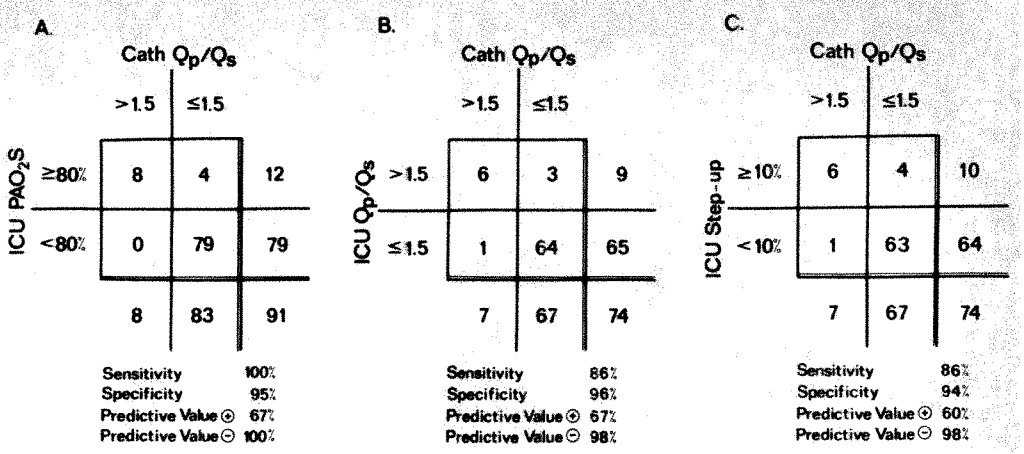
"Truth" tables relating immediate postoperative data to pulmonary to systemic flow ratio 1 year after surgery in all 98 patients. **A**, intensive care unit (ICU) pulmonary arterial oxygen saturation (PAO_2S) of 80% or greater as predictive of 1 year postoperative catheterization (Cath) pulmonary to systemic flow ratio (Qp/Qs) greater than 1.5. **B**, intensive care unit Qp/Qs greater than 1.5 as predictive of catherization Qp/Qs greater than 1.5. **C**, intensive care unit step-up in oxygen saturation from right atrium to pulmonary artery of 10% or greater as predictive of catheterization Qp/Qs greater than 1.5.



a pulmonary to systemic flow ratio. A pressure recording of a pullback of the pulmonary artery catheter from the pulmonary artery across the right ventricular outflow tract to the right ventricle allows determination of obstruction at this level. These measurements are routinely performed 24 hours after surgery. In addition, 1 year postoperative hemodynamic evaluation by cardiac catheterization is recommended to all patients who have undergone repair of tetralogy of Fallot.

Methods

Patients: The records of all patients who underwent repair of tetralogy of Fallot at Children's Hospital Medical Center, Boston between January 1974 and June 1979 were examined. Of these, we studied 98 patients for whom data existed pertaining to intracardiac shunting or right ventricular outflow tract obstruction, or both, in the early postoperative period and at 1 year postoperative catheterization. Four patients with additional major intracardiac lesions and 25 who required an external conduit for right ventricular outflow tract reconstruction were excluded. In addition, there are 5 patients for whom no early postoperative data are available and 68 patients who have not undergone cardiac catheterization since surgery.

Early postoperative studies: These were performed 18 to 36 hours after surgery. No patient was receiving supplemental oxygen at a fractional inspired oxygen concentration greater than 0.5. Blood samples were drawn simultaneously from the right atrial, pulmonary arterial, left atrial, and systemic arterial catheters and oxygen saturation measurements were made. Pullback pressure tracings from the pulmonary artery to the right ventricle (or right ventricular pressure tracing alone if the catheter was in the right ventricle) were recorded. The right ventricular outflow tract pressure gradient was determined by subtracting the peak pulmonary artery systolic pressure from the peak right ventricular systolic pressure.

One year follow-up studies: At cardiac catheterization, pulmonary to systemic flow ratios were determined by the Fick principle using pulmonary artery, superior vena cava, and systemic arterial oxygen saturations obtained during the rapid pullback of the catheter from pulmonary artery to superior vena cava while measuring oxygen consumption. If there was no step-up in oxygen saturation but left ventricular angiography revealed a tiny residual ventricular septal defect, the patient was arbitrarily assigned a pulmonary to systemic flow ratio of 1.1. The right ventricular outflow tract gradient was determined by subtracting the peak distal pulmonary arterial systolic pressure from the peak right ventricular systolic pressure recorded during the same catheter pullback.

Analysis of data: "Truth" tables were constructed comparing immediate postoperative data with those obtained at 1 year postoperative catheterization. Immediate postoperative data were compared with the pulmonary to systemic flow ratio and the right ventricular outflow tract gradient determined at cardiac catheterization.

Results

Residual left to right shunts: The immediate postoperative pulmonary to systemic flow ratio, the absolute step-up in oxygen saturation from the right atrium to the pulmonary artery, and the oxygen saturation in the pulmonary artery were compared with the pulmonary to systemic flow ratio at 1 year postoperative catheterization (Fig. 1 and 2). All 3 measurements were highly sensitive in identifying patients with a hemodynamically significant left to right shunt. More data were available for analysis with use of pulmonary arterial oxygen saturation alone because of malfunction of

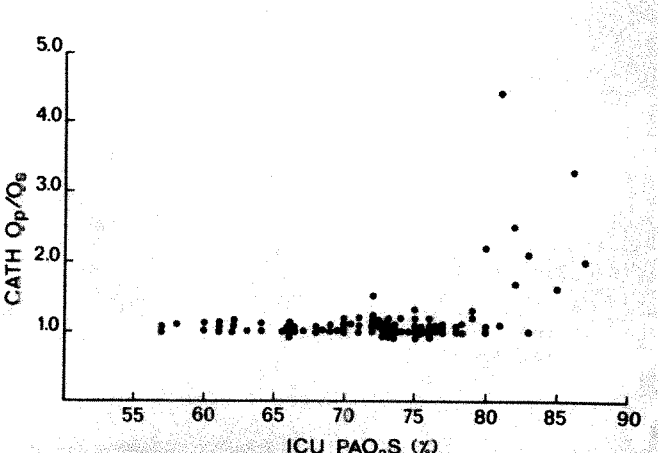


FIGURE 2. Relationship of pulmonary arterial oxygen saturation (PAO_2S) in the immediate postoperative period in the intensive care unit (ICU) to the pulmonary to systemic flow ratio (Qp/Qs) at catheterization (Cath) 1 year after surgery in all patients.

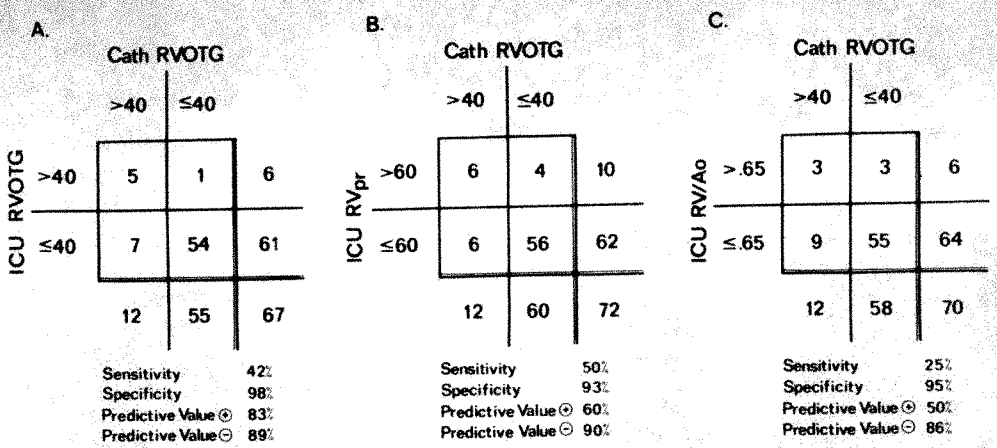

FIGURE 3. "Truth" tables relating immediate postoperative data to the right ventricular outflow tract gradient 1 year after surgery in all patients. **A**, intensive care unit (ICU) right ventricular outflow tract gradient (RVOTG) greater than 40 mm Hg as predictive of 1 year postoperative catheterization (Cath) right ventricular outflow tract gradient greater than 40 mm Hg. **B**, intensive care unit right ventricular pressure (RV_{pr}) greater than 60 mm Hg as predictive of catherization right ventricular outflow tract gradient greater than 40 mm Hg. **C**, intensive care unit right ventricular to systemic arterial pressure ratio (RV/Ao) greater than 0.65 as predictive of catheterization right ventricular outflow tract gradient greater than 40 mm Hg.

some of the right atrial catheters. One patient had a right atrial and pulmonary arterial oxygen saturation of 87% in the immediate postoperative period and a pulmonary to systemic flow ratio of 2.0 at catheterization and was identified as having a significant residual shunt only if the pulmonary artery oxygen saturation alone was evaluated. Table I presents the relevant intensive care unit and catheterization data on the 8 patients with a pulmonary to systemic flow ratio greater than 1.5 at catheterization. With the exception of the 1 patient mentioned (Case 6), all patients could be identified in the intensive care unit by either a pulmonary to systemic flow ratio greater than 1.5, a pulmonary arterial oxygen saturation of 80% or greater, or an increase in oxygen saturation of at least 10%.

Residual right ventricular outflow tract obstruction: The immediate postoperative right ventricular outflow tract gradient, the right ventricular pressure, and the right ventricular to systemic arterial pressure ratio were compared with the right ventricular outflow tract gradient at 1 year postoperative catheterization (Fig. 3 and 4). None of these variables was highly sensitive in identifying patients with significant late residual obstruction. Table II summarizes the pressure data on the 12 patients with a right ventricular outflow tract gradient greater than 40 mm Hg at follow-up catheterization. Only 6 of these patients had evidence of significant residual right ventricular outflow tract obstruction in the immediate postoperative period.

TABLE I Summary of Data on 8 Patients With a Significant Left to Right Shunt (Qp/Qs Greater Than 1.5) at 1 Year Postoperative Catheterization (Cath)

Patient	Cath Qp/Qs	ICU PAO_2S (%)	ICU Qp/Qs	ICU O_2 Step-Up (%)
6	2.0	87*	1.0	0
18	1.7	82*	1.9*	12*
27	3.3	86*	3.6*	26*
69	2.2	80*	. . .	. . .
70	2.5	82*	2.4*	23*
78	1.6	85*	2.1*	15*
93	2.1	83*	1.9*	13*
96	4.4	81*	2.0*	10*

Discussion

The principal aims of surgical repair of tetralogy of Fallot are the abolition of intracardiac shunting and the relief of right ventricular outflow tract and pulmonary arterial obstruction. Failure to adequately close an interventricular communication results in left to right shunting if the obstruction to pulmonary blood flow is relieved. The adverse effects of such a shunt after repair of tetralogy of Fallot have been demonstrated.[10] Although the significance of mild to moderate persistent right ventricular outflow tract obstruction has not been clarified, recent evidence suggests that it contributes to ventricular arrhythmias, which in turn have been correlated with late sudden death.[11]

Diagnosis and management of residual postoperative left to right shunt: The detection of a significant left to right shunt in patients immediately after repair of tetralogy of Fallot is often difficult on clinical examination. Systolic and diastolic murmurs associated with reconstruction of the right ventricular outflow tract and some degree of congestive cardiac failure are almost universal in the early postoperative period. Noninvasive diagnostic techniques such as echocardiography and radionuclide angiocardiography lose specificity in the presence of pulmonary regurgitation. The persistence of congestive failure beyond several months indicates a likelihood of significant hemodynamic defects; earlier recognition followed by repair is possible.

The techniques employed in this study were highly sensitive in identifying patients shown to have a pulmonary to systemic flow ratio greater than 1.5 one year after surgery. All 8 patients with a significant shunt at 1 year postoperative catheterization had a pulmonary arterial oxygen saturation of 80% or greater in the intensive care unit. Such shunting can result from incomplete closure of the malalignment ventricular septal defect of tetralogy of Fallot or from the presence of additional defects. We currently recommend early confirmation of shunt size and localization of the defect by cardiac catheterization and left ventricular angiography. Patients shown to have a pulmonary to systemic flow ratio greater than 1.5 undergo closure of the residual defect. The importance of angiographic localization of residual defects was recently stressed by the demonstration that 14% of infants with tetralogy of Fallot have multiple or complicated ventricular septal defects.[12]

Diagnosis of residual postoperative right ventricular obstruction: Our ability to identify patients in the immediate postoperative period who had significant residual right ventricular outflow tract obstruction demonstrated at 1 year postoperative catheterization was not striking. Measurement of the right ventricular outflow tract gradient in the intensive care unit identified only 5 of 12 patients, but with only 1 false-positive result. Measurement of right ventricular pressure or the right ventricular to systemic arterial pressure ratio did not identify significantly more patients but did have a higher rate of false-positive diagnoses. There are several possible explanations for the poor specificity of the measurements. Right ventricular outflow tract gradients measured in the intensive care unit would fail to identify patients with distal pulmonary arterial branch obstruction if the monitoring catheter were in the contralateral or main pulmonary artery. However, one would then expect an elevated right ventricular pressure. This was not always the case (Table II). The failure to observe an elevated right ventricular pressure as well as the low right ventricular outflow tract gradient measured in the intensive care unit in patients with significant obstruction 1 year later may indicate that right ventricular outflow tract gradients increase with time. It is interesting to note that several centers[1,3] employ intraoperative measurement of the right ventricular to systemic arterial pressure ratio as an index of the adequacy of right ventricular outflow tract reconstruction. Our data suggest that this may fail to

TABLE II Summary of Data on 12 Patients With a Significant Right Ventricular Outflow Tract Gradient (Greater Than 40 mm Hg) at 1 Year Postoperative Catheterization (Cath)

Patient	Cath RVOTG (mm Hg)	Cath RVP (mm Hg)	ICU RVOTG (mm Hg)	ICU RVP (mm Hg)	ICU RV/Ao Ratio

ICU = intensive care unit; RV/Ao = right ventricular to systemic arterial pressure ratio; RVOTG = right ventricular outflow tract gradient; RVP = right ventricular pressure.
* Values predictive of residual right ventricular outflow tract obstruction as shown in Figure 3.

identify significant residual obstruction. In addition, others[13] have recently shown that such measurements may be misleadingly high.

Our current recommendations for hemodynamic evaluation of patients after repair of tetralogy of Fallot include (1) measurements of pulmonary arterial oxygen saturation and right ventricular outflow tract gradient in the intensive care unit after surgery, (2) early catheterization of patients with a pulmonary arterial oxygen saturation greater than 80% or a right ventricular outflow tract gradient greater than 40 mm Hg, and (3) catheterization of all patients 1 year after surgery.

Pediatric Cardiac Catheterization With Same-Day Discharge

J. DEANE WALDMAN, MD, TERRANCE S. YOUNG, BS, STANLEY J. PAPPELBAUM, MD, SEARLE W. TURNER, MD, STANLEY E. KIRKPATRICK, MD, and LILY M. GEORGE, MB, BS, MRCP (UK)

A system was developed for cardiac catheterization in children without overnight hospital stay (called same-day discharge). Over a 4 year period, 233 children (aged 5 weeks to 20 years) had catheterization with same-day discharge, staying an average of 11.8 hours in the hospital. In all but 1, no problems occurred after hospital discharge; 1 child required readmission for psoas tendinitis after retrograde aortography. Same-day discharge was safely applied regardless of the patient's age, diagnosis, and use of systemic heparinization, large-bore sheaths, retrograde arterial catheterization, or cineangiography. The hospital-related cost of pediatric cardiac catheterization was reduced 29% compared with that of the standard 42 hour hospital stay.

Same-day discharge provides attractive elements to the physician and institution involved in cardiac catheterizations, for example: (1) improved medical care by a decrease in the length of hospitalization, (2) a significant reduction in medical costs, and (3) elimination of time pressure in training and teaching as well as therapeutic decision-making. Critical factors for the successful application of same-day discharge are coordination of multiple health care professionals and physician judgment of the patient's clinical status. We speculate that reassessment of other hospital-oriented procedures may foster the development of methods for improving medical care or reducing cost, or both.

In 1976, we posed the question, "Must cadiac catheterization in children require overnight hospital stay?" Theoretical advantages of shortening the length of hospitalization include lessening of psychosocial stress, more efficient use of scarce resoures (such as hospital beds and nurses), and, of course, reduction in the cost of medical care. A system was developed at the San Diego Children's Hospital for admission, cardiac catheterization, and discharge on 1 day (same-day discharge). This system involved the timed interaction of: (1) anesthesia service, (2) cardiac catheterization laboratory, (3) cardiology service, (4) clinical laboratories, and (5) nursing staff.

From the Pediatric Cardiology Medical Group, The Cardiac Center at Children's/Sharp Medical Complex, and the University of California at San Diego, School of Medicine, San Diego, California. Manuscript received December 8, 1981; revised manuscript received April 13, 1982, accepted April 16, 1982.

Address for reprints: J. Deane Waldman, MD, Division of Cardiology, Children's Hospital of San Diego, 8001 Frost Street, San Diego, California 92123.

Methods

Patients: From January 1, 1977 to December 31, 1980, 645 cardiac catheterizations were performed in children (under 21 years of age) at the Children's Hospital of San Diego (Table I). The study group consists of 418 studies performed on an elective basis (65% of all pediatric catheterizations). Of these, 233 were performed with same-day discharge.

Hospital charts and catheterization logs were reviewed to determine: (1) patient demography, (2) diagnosis, (3) technical details of catheterization, (4) complications/hospital readmission, and (5) elapsed times (admission to catheterization, catheterization procedure, and catheterization to discharge). The decision regarding same-day discharge or overnight hospital stay was made by the physicians performing the catheterization (4 individuals).

Data analysis: The information was coded on IBM punch cards, tabulated, and manipulated on a Burroughs 7800 computer. Chi-square analysis was utilized for comparisons of nominal data (such as demographic or catheterization characteristics of patient groups) and t tests were used for analysis of ordinal data (primarily data measured in time).

TABLE I Pediatric Cardiac Catheterization Experience (1977 through 1980)

	1977	1978	1979	1980	Total
Total catheterizations	134	121	164	226	645
Elective catheterizations	88	82	106	142	418
Same-day discharge	20 (23%)	28 (34%)	72 (68%)	114 (80%)	233 (56%)
Overnight hospital stay	68	54	34	28	185
For specific reason	7	4	9	13	. . .
Without specific reason	61	50	25	15	. . .

Results

Reason for overnight stay versus same-day discharge: Year-by-year analysis of the 233 same-day discharges (Table I) shows a progressive increase in the percentage of the 418 elective catheterizations performed with same-day discharge from 23% in 1977 to 80% in 1980. Of the 418 children, 185 (44%) spent 1 or more nights in the hospital: 114 spent 1 night, 64 spent 2 nights, and 7 stayed 3 or more nights after catheterization. Specific reasons for overnight hospital stay included: (1) fever or emesis in 7, (2) arrhythmias in 7, (3) catheterization limb problems (spasm or thrombus) in 4, (4) cerebral embolus in 3, (5) hypercyanotic spells in 2, and (6) technical or equipment problems in 10. Overnight hospital stay without specific reason occurred in 69% (61 of 88) of elective pediatric catheterization in 1977, compared with only 11% (15 of 142) in 1980.

Clinical differences in the 2 patient groups: Children under 1 year of age stayed overnight more frequently ($p < 0.05$) than having same-day discharge; in the older children there was no significant difference between same-day discharge and overnight hospital stay. Median weight was similar in same-day discharge (13.3 kg) and overnight hospital stay (12.3 kg) groups. Comparing same-day discharge and overnight hospital stay groups by diagnosis, there was a preference to send home children with obstructions but keep overnight those with left-to-right shunts ($p < 0.05$).

Ninety percent (377/418) of the patients had both right and left heart catheterization; a similar number (375/418) received general (ketamine) anesthesia. There were no significant differences between the same-day discharge and overnight hospital stay groups in the approach to the aorta, use of heparin, volume of contrast agent, number of angiograms, or mean sheath size.

Comparing the chronology of catheterization in same-day discharge and overnight hospital stay groups, significant differences ($p < 0.001$) were seen in time before catheterization (5.8 versus 15.5 hours, respectively) and time after catheterization (5.0 versus 19.7 hours, respectively). Time of the catheterization itself was greater in patients staying overnight than in those with same-day discharge in 1977 ($p < 0.003$) and in 1978 ($p < 0.02$); in 1979 and 1980, time of catheterization was not significantly different in the two groups.

Complications: There were no postdischarge complications in 232 of 233 patients with same-day discharge. Specifically, no patient required hospital readmission for bleeding, endocarditis, dehydration, or thromboembolism. No significant hematoma or groin infection was noted in any patient. In 1 child, psoas tendinitis developed after retrograde aortography and the child was readmitted 6 days after catheterization for therapy of the hip discomfort.

Discussion

The basic question we asked was whether the length of hospitalization for pediatric cardiac catheterization could safely be shortened, resulting in lower costs, decreased risk of hospitalization,[1] and reduction of patient and family anxiety. In most major pediatric cardiac centers, the standard approach to cardiac catheterization involves hospital admission on day 1, catheterization on day 2, and discharge that afternoon or on day 3. The reasons for this 2 to 3 day hospital stay are related to: (1) preparatory noninvasive tests before catheterization, (2) work-up of the patient by physicians-in-training, (3) need to perform several catheterizations per day, (4) possibly increased catheterization time due to clinical research or involvement of physicians-in-training, and (5) observation of the patient.

A system for same-day discharge: By coordinating the activities of all those involved in pediatric catheterization (cardiology and radiology departments, nursing, clinical and catheterization laboratories, and anesthesia and cardiology services), a system was developed as outlined in Table II. Initial complete evaluation of the patient, patient and parent education as well as instruction of the physicians-in-training were usually done on an outpatient basis before hospitalization. A 2 hour time frame was adequate for the majority of studies, including those with clinical research protocols (40% of the catheterizations in 1980).

Acceptance of the same-day discharge procedure was immediate in patients and their families but gradual among medical professionals. During the study period

TABLE II Typical Chronology for Catheterization With Same-Day Discharge

Time	Event
07:30	Hospital admission
08:00	Venipuncture for blood tests
08:30	Examination by cardiologist, anesthesiologist, and cardiac nurse
09:30	Noninvasive tests, if necessary
12:00	Catheterization
14:30	Recovery room
16:30	Return to ward; examination by cardiologist
18:30	Discharge

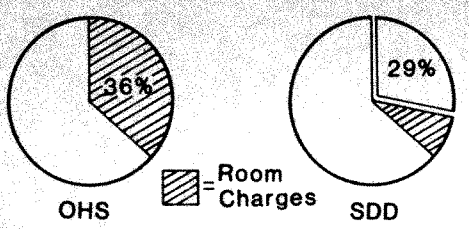

FIGURE 1. Financial savings with same-day discharge. **Cross-hatched areas** indicate room charges with overnight hospital stay (OHS) and same-day discharge (SDD); a 29% reduction in cost is seen with same-day discharge.

(1977 through 1980) the percentage of patients with overnight hospital stay without specific reason decreased from 69 to 11%, indicative of increasing confidence in the safety of the same-day discharge protocol.

Neither the size of the patient nor the diagnosis per se was considered an impediment to same-day discharge. The crucial element was the clinical condition and stability of the patient. No difficulties were encountered with same-day discharge of patients under 1 year of age with compensated heart failure, whether acyanotic or cyanotic, and with or without pulmonary artery hypertension.

Complications: Observation of the groin after catheterization is a common reason for overnight hospital stay. Our experience suggests a reappraisal of this policy. Cardiac catheterization in children almost always involves a femoral venous approach which, beyond the 1st month of life, is virtually risk free. Retrograde arterial catheterization was necessary in 48% of the children. There were 5 arterial complications; in 4 (2 with spasm and 2 with thrombus requiring embolectomy) the problem was immediately evident and the children were kept overnight. The 5th child was discharged the day of catheterization; his subsequent readmission for psoas tendinitis was the only complication in the entire group of 233 children with same-day discharge. Other significant complications of catheterization such as persistent arrhythmia, cyanotic spell, or thromboembolism (total of 13 instances (3%) in 418 elective studies) were readily apparent after the procedure. This experience coincides with earlier reports[2,3] that major complications are usually obvious during or immediately after catheterization.

Constitutional symptoms such as low grade fever, nausea, and emesis are not uncommon after cardiac catheterization. Fever after catheterization has been related to the number of angiograms or the catheter-cleansing techniques, or both, and is not considered indicative of bacteremia.[4,5] Nausea and emesis are occasionally seen after catheterization, probably related to the administration of sedative medications or contrast agents; these side effects are usually short-lived and adequate hydration is temporarily maintained by intravenous fluids. Therefore, we conclude that it is safe to utilize same-day discharge in a child who: (1) is in a hemodynamically stable state, (2) does not require urgent surgery, (3) has no limb complications, and (4) is tolerating oral liquids.

Previous studies: There are no prior published data with which to compare our experience (see Addendum). Rosengart and Sapin of the Kaiser-Permanente Medical Group in Los Angeles (personal communication) have used same-day discharge in over 109 children without complications. Gulde et al.[6] recently presented a large adult experience in an office-located cardiac catheterization laboratory and noted no increase in mortality or morbidity. In 1981 Perrigo et al.[7] reported a 20 month trial of outpatient cardiac catheterization in 224 adults with a 28% decrease in the cost of catheterization.

Hospital costs: Review of our 1980 financial data reveals significant savings realized by same-day discharge (Fig. 1). The average hospital charge for the catheterization procedure plus medications and necessary noninvasive studies averaged $1,093; the room charge for 3 days and 2 nights in the hospital was $615, or 36% of the total hospital bill if the standard approach to pediatric catheterization had been employed. Utilizing same-day discharge, the average time in the hospital was 11.8 hours, which translated to a room charge of $122, a savings of 80% on the room charge and 29% on the total hospital bill. No additional physician charges were created by the use of same-day discharge.

In many centers, children with straightforward defects such as atrial septal defect and coarctation of the aorta have cardiac catheterization and surgery on a single hospital admission. This practice is intended to decrease the length of hospital stay. In a typical case, the child is admitted on Monday, has catheterization on Tuesday, observation on Wednesday, and surgery on Thursday, resulting in a total of 3 nights in hospital before surgery. A same-day discharge approach with subsequent hospital admission results in only 1 night in hospital before surgery, achieving a large reduction in preoperative room charges.

Psychological effects: Of major import is the emotional well-being of the patient and family. Hospitalization and cardiac catheterization generally produce psychological stress in the child because of: (1) anxiety over separation from family, (2) anxiety over unfamiliar (therefore threatening) people, places, and objects, and (3) fear of pain or (in older children) death.[8–10] In addition to the patient's psyche, the family is also under considerable stress. Although preparatory education may alleviate some anxiety,[10,11] the promise that the patient can probably sleep in his or her own bed that night is a major source of relief to both the patient and his family.

Time pressure in teaching and therapeutic decision-making: An additional advantage of the same-day discharge approach to catheterization is the removal of time pressure in teaching and therapeutic decision-making. With the overnight hospital stay approach, the resident or fellow must do the work-up on the patient around the varying schedules of radiology, clinical laboratories, hospital rounds, and the busy in-hospital

staff physician. With the same-day discharge approach, the attending physician and trainee may discuss the findings, rationale for study, and technical considerations well in advance of the study in an unhurried fashion. Finally, the system of catheterization and surgery on 1 admission requires analysis of data, review of angiograms, and team conference during the 1 day between study and operation; the same-day discharge approach with subsequent hospital admission allows consideration of the findings and operative approach as well as possible additional outside consultations without time pressure.

Implications

Elective cardiac catheterization of children with same-day discharge can be performed safely, with consequent decrease in both financial and psychological cost. Even those patients not residing close to the medical center can use a nearby temporary residence as a surrogate home. Our study demonstrates that the goals of reducing medical costs and improving quality of care need not be mutually exclusive. In a recent editorial, Egdahl[12] stated that "many well-established methods of patient care overuse hospitalization." Our data indicate the hospitalization can be shortened for pediatric cardiac catheterization. We believe that reassessment of other expensive hospital-oriented procedures beyond the sphere of congenital heart disease may produce innovative ways to deliver high quality care at a lower cost.

Addendum

During review of this manuscript, Cumming[13] reported a 12 year experience with outpatient cardiac catheterization in children. In 1980, 80% of their children were studied as outpatients, a percentage identical to our same-day discharge experience during the same year. A slightly higher complication rate (1.0%) was noted by Cumming, but most of the complications (9 of 13) did not require hospital admission. The major points on which Cumming and our group concur are (1) the safety of cardiac catheterization in children without overnight hospital stay, and (2) the reduction in stress achieved by this approach.

We differ with Cumming in 2 areas: cost reduction and loss of teaching experience. In contrast to the procedure developed in Canada, no additional charges were created by our same-day discharge approach, which achieved a 29% reduction in hospital charges. Second, we believe that teaching was enhanced by the same-day discharge technique. In most centers, the child receives a work-up by a trainee who has extensive inpatient responsibilities, *all* more urgent than the child admitted for elective catheterization, leaving little time for learning from this exposure. With our system, the same trainee sees the patient in the office, participates in the precatheterization teaching, attends the catheterization itself, reviews the data with the physician performing the catheterization, and attends the regional conference. Thus, teaching appears to be improved rather than impaired by same-day discharge.

Compression of Intrapulmonary Bronchi by Abnormally Branching Pulmonary Arteries Associated With Absent Pulmonary Valves

MARLENE RABINOVITCH, MD, STAFFORD GRADY, MD, IVAN DAVID, MD, RICHARD VAN PRAAGH, MD, URSULA SAUER, MD, KONRAD BUHLMEYER, MD, ALDO R. CASTANEDA, MD, and LYNNE REID, MD, *with the technical assistance of* DONNA K. SILVA

In 3 patients with absent pulmonary valve syndrome and absent ductus arteriosus, the lungs were injected and analyzed postmortem using morphometric techniques. Two patients had tetralogy of Fallot and 1 had D-transposition of the great arteries, the latter being the first autopsy-proved case of absent pulmonary valve with transposition. In addition to the expected dilatation of the central pulmonary arteries and compression of the mainstem bronchi, postmortem pulmonary arteriography revealed a bizarre pattern of hilar branching. Instead of single segmental arteries, tufts of arteries arose which entwined and compressed the intrapulmonary bronchi. In all 3 patients the histologic structure of the pulmonary arteries was abnormal. The elastic lamina of the media of the right and left pulmonary arteries were increased in number outside the lung, but were decreased within the lung. At both sites, the elastic laminae were thickened and fragmented. In the 2 ventilator-dependent patients, there was slight medial hypertrophy and extension of muscle into normally nonmuscular arteries. In 1 of the 2 cases in which the number of bronchial generations was counted, they were decreased, and in the 1 case in which bronchial count was unknown, alveolar multiplication was severely impaired. Therefore, our data may explain why, in some patients with absent pulmonary valve syndrome, relief of compression of the mainstem bronchi alone does not appreciably alleviate or reverse severe respiratory disease.

The absent pulmonary valve syndrome includes absence or rudimentary development of the pulmonary valve leaflets, pulmonary annular hypoplasia, and dilated pulmonary arteries. This syndrome is usually associated with tetralogy of Fallot,[1-14] but can occur with an intact ventricular septum[15-20] and rarely may be associated with D-transposition of the great arteries.[21] There is a high mortality among infants because they usually develop airway obstruction and pulmonary infections which are thought to be due to compression of the mainstem bronchi by the markedly enlarged central pulmonary arteries.

We report herein on 3 infants with the absent pulmonary valve syndrome who were studied postmortem using arteriographic and morphometric techniques. These investigations revealed a previously unreported branching anomaly of pulmonary arteries within the lungs. One of these patients is the first autopsied case of absence of the pulmonary valve with D-transposition of the great arteries.

Methods

Complete postmortem examination was carried out in each case, the heart and lungs being removed en bloc. The cardiac anomalies were diagnosed. The main pulmonary artery was cannulated and injected with a 50°C barium-gelatin mixture at 100 cm water pressure using previously described tech-

niques.[22] The lung was then inflated through the trachea with 10% formaldehyde at 36 cm water pressure and was fixed inflated for 1 week. Lung volumes were determined by water displacement before and after fixation and arteriograms were taken at 45 kV with a fixed tube distance of 60 cm.

In Cases 1 and 3, the bronchial generations of the lower lobe of the left lung were counted using a dissecting microscope; this was not possible technically in Case 2. The peripheral bronchial branches were reconstructed by means of step sections 50 μm apart. From each case, a 1 cm^2 section was selected at random from each lobe of both lungs. In addition, blocks were taken to provide cross-sections of the main pulmonary artery, the right pulmonary artery, and the segmental axial artery of the right middle lobe. In the case of the latter artery, blocks were examined every 1 cm from the hilum to the periphery.

Alveoli: Alveolar development was evaluated in 3 ways. Alveolar size was assessed as the numbr of alveoli per square centimeter; total alveolar number in each lung was calculated and radial alveolar counts were taken. The latter, according to the method described by Emery and Mithal,[23] consists of drawing a perpendicular line from the center of a respiratory bronchiolus to the periphery, be that a connective tissue septum or a pleural surface. The number of alveoli transected is a measure of alveolar development at any age.

Arteries: In each section, each artery was landmarked according to its accompanying airway (whether preacinar, terminal bronchiolus, respiratory bronchiolus, alveolar duct, or alveolar wall) and examined for structure (whether muscular, that is, completely surrounded by a muscular coat, having both an external and internal elastic lamina; or partially muscular, that is, partially surrounded; or nonmuscular). Using a calibrated eyepiece micrometer, the external diameter of each artery was measured, and for muscular and partially muscular arteries, the thickness of the medial muscular coat was calculated as a percentage wall thickness according to the formula: Percentage wall thickness = (2 × wall thickness/external diameter) ×100. In each field (magnification ×200) the number of arteries and alveoli were counted. Arterial concentration was calculated per unit area and as the number of arteries per 100 alveoli.

Veins: Because veins had not been injected, morphometric data were not available but muscularity was assessed qualitatively.

Bronchi, bronchial arteries, and connective tissue: The bronchi were inspected qualitatively for size and for the presence and amount of cartilage. Bronchial arteries were evaluated qualitatively for number, size, and presence of anastomoses with pulmonary arteries that were judged by whether they had filled with contrast material from the pulmonary artery injection. The amount of connective tissue within the bronchovascular bundle was also assessed.

Normal values: Normal values, obtained in 2 age-matched control infants studied by 1 of us (MR), were similar to those previously reported.[22] To determine those changes in the pulmonary vessels peculiar to the 3 cases in this report, we also compared the findings with those from a 4 month old infant with severe postnatal pulmonary hypertension associated with a double-outlet right ventricle and with those from patients with similar congenital heart defects that we previously reported on.[24,25]

Results

Clinical Findings

Case 1: This male infant was a fraternal twin who was born at term with a birth weight of 3.6 kg after an uneventful pregnancy in a 26 year old gravida 1, para 1. His co-twin was normal. In our patient, cyanosis and marked respiratory distress were noted from birth. A grade 3/6 systolic and diastolic murmur was heard along the left sternal border and the 2nd heart sound was single. The pulses were full and equal, and the liver was firm and palpable 2 cm below the right costal margin. At an FIO_2 of 100%, the arterial blood gases were as follows: pO_2 95 torr, pCO_2 110 torr, and pH 6.6. The infant was intubated and ventilated, and given bicarbonate and digoxin intravenously.

The chest radiograph showed moderate cardiomegaly, diminished pulmonary blood flow, prominent pulmonary arteries, overinflation of the right lung, and underinflation or hypoplasia of the left lung. The electrocardiogram revealed a QRS axis of +120° and right ventricular hypertrophy.

The 2 dimensional echocardiogram was interpreted as showing transposition of the great arteries (S,D,D), a large malalignment type of ventricular septal defect, anterior displacement of the infundibular septum, pulmonary artery overriding of the ventricular septum, massive dilatation of the main pulmonary artery, abnormal pulmonary valve with thickened leaflets and decreased mobility, inability to exclude patent ductus arteriosus because of dilatation of the main pulmonary artery, flattening of the left atrium by the dilated right pulmonary artery, patent foramen ovale, and no evidence of subaortic stenosis.

Cardiac catheterization (Table I) and biplane cineangiocardiography (Fig. 1) were performed when the infant was 8 hours old. The diagnosis of D-transposition of the great arteries with absent pulmonary valve was confirmed and balloon atrial septostomy performed. The infant subsequently became progressively more difficult to ventilate, bilateral pneumothoraces developed requiring chest tube drainage, and the infant died on the 4th day of life.

Case 2: This female infant was born at term with a birth weight of 2.5 kg after an uneventful pregnancy in a 26 year old gravida 1, para 1. She was mildly cyanotic at 16 hours of age. A grade 3/6 harsh systolic and diastolic murmur was heard at the upper left and right sternal borders and the 2nd heart sound was single. Pulses were full and equal and the liver edge was palpable 2 cm below the right costal margin. Chest radiographs showed a right aortic arch, mild cardiac enlargement, diminished pulmonary blood flow, and markedly dilated pulmonary arteries. The electrocardiogram revealed a QRS axis of +90° and biventricular hypertrophy. At an FIO_2 of 80%, arterial blood gases were as follows: pO_2 44 torr, pCO_2 32 torr, and pH 7.39.

A 2 dimensional echocardiogram showed normally related great arteries, a large malalignment type of ventricular septal defect, pulmonary annular hypoplasia, no pulmonary leaflets, and massive dilatation of the main, right, and left pulmonary arteries.

Cardiac catheterization and angiocardiography at 2 days of age confirmed the diagnosis of tetralogy of Fallot with an absent pulmonary valve. The coronary artery anatomy was normal and no ductus arteriosus or ductus diverticulum was seen.

Ao = aorta; FIO_2 = fraction of inspired oxygen concentration; PA = pulmonary artery; PV = pulmonary vein; RA = right atrium; RV = right ventricle; (S/D) = systolic/diastolic; SVC = superior vena cava; — = mean value; . . . = value not obtained.

Mild congestive heart failure was treated with digoxin and diuretics. Although the infant initially responded well enough to be discharged from the hospital, she failed to thrive and was readmitted at 10 weeks of age weighing slightly less than her birth weight. Repeat cardiac catheterization revealed a large left-to-right shunt, and pulmonary venous desaturation suggesting lung disease.

Surgical repair was undertaken the following day using deep hypothermic circulatory arrest. The aneurysmally dilated main pulmonary artery was incised and tapered. A pericardial patch was placed across the pulmonary annulus. The ventricular septal defect was closed with a Dacron® patch and a patent foramen ovale was sutured. After an initially satisfactory postoperative course, the patient had an episode of sudden unexplained bradycardia and hypotension from which she could not be resuscitated.

Case 3: This female infant was born at term with a birth weight of 3.9 kg after an uneventful pregnancy in a 24 year old gravida 2, para 2; she was cyanotic 15 minutes after birth and was referred to the Deutsches Herzzentrum Munchen in Munich, West Germany. A grade 3/6 systolic and diastolic murmur was heard all over the precordium and the 2nd heart sound was single. Pulses were full and there was no hepatosplenomegaly. Chest radiograph showed a left aortic arch, normal heart size, dilated hilar pulmonary arteries, and decreased

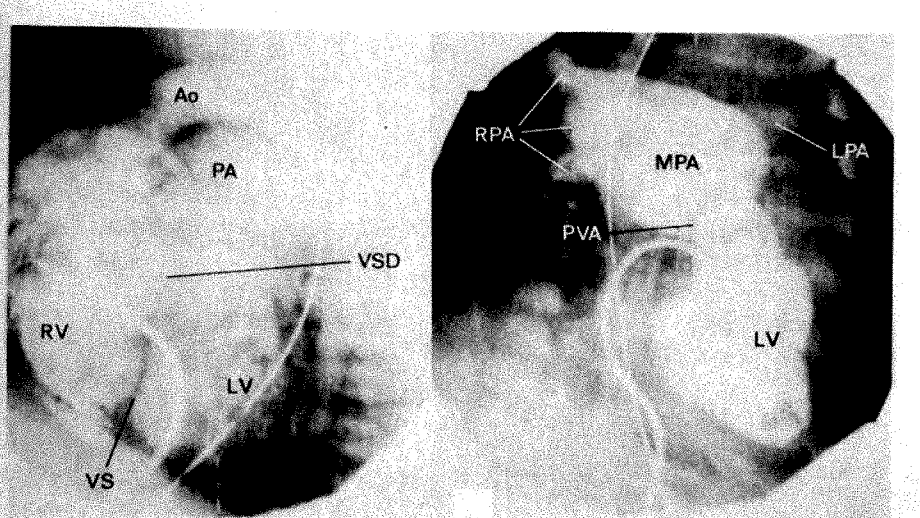

FIGURE 1. Left, lateral projection of the selective right ventricle (RV) injection. Transposition of the great arteries (TGA), marked dilatation of the pulmonary artery (PA), and right-to-left shunting of contrast medium through the large subpulmonary ventricular septal defect (VSD), the morphologically left ventricle (LV), and the ventricular septum (VS) are seen. **Right,** angulated right anterior oblique projection of selective left ventricle injection showing a somewhat narrowed pulmonary valve annulus (PVA) and aneurysmal dilatation of the main pulmonary artery (MPA), right pulmonary artery (RPA), and left pulmonary artery (LPA). Ao = aorta.

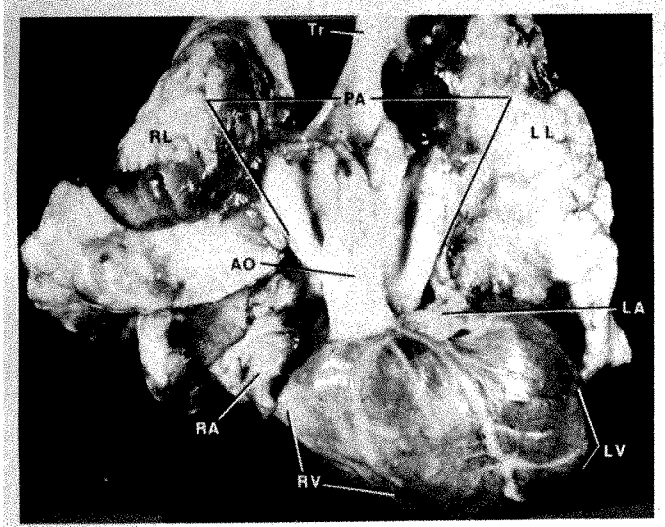

FIGURE 2. Case 1. Heart and lung specimen, external frontal view. The ascending aorta (Ao) arises from the morphologic right ventricle (RV) to the right of the enormously dilated pulmonary artery (PA). The pulmonary artery originates in the morphologic left ventricle (LV), to the left and posterior relative to the plane of the anterior descending coronary artery, which indicates the location of the interventricular septum. LL and RL = left and right lungs, respectively; Tr = trachea.

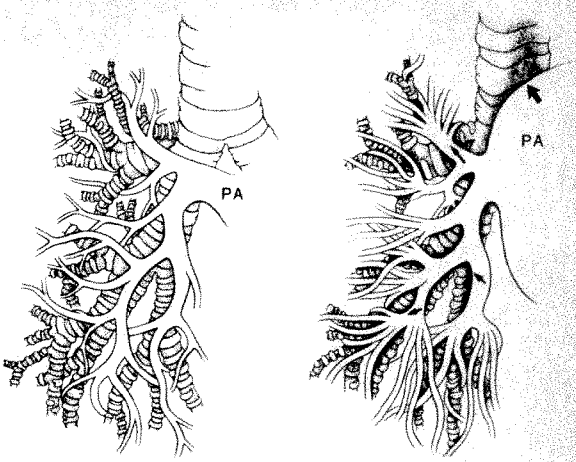

FIGURE 3. Diagram of (**left**) the normal pulmonary artery branching and (**right**) the abnormal pattern seen in our cases of absent pulmonary valve syndrome. peripheral vascular markings. Because of initial hypoxemia, hypercarbia, and acidosis, the infant was placed on a respirator. Arterial blood gases on the ventilator at an FIO_2 of 80% were as follows: pH 7.38, pO_2 38, and pCO_2 42 torr. Cardiac catheterization at 4 days of age confirmed the clinical diagnosis of tetralogy of Fallot with absent pulmonary valve. No ductus arteriosus or ductus diverticulum was seen. The infant became progressively more difficult to ventilate, had recurrent pneumothoraces, and died at 3 months of age.

Postmortem Findings

Gross morphology: **Case 1:** Bilateral pneumothoraces were found at autopsy. Both lungs were distended with air and bullae were present (Fig. 2); the left lung appeared disproportionately smaller than the right. Situs solitus of the viscera and atria (S) was apparent, as well as D-loop (noninverted ventricles [D]), and transposition of the great arteries with the aortic valve lying to the right (dextro or D) relative to the pulmonary valve (S,D,D). The pulmonary artery and branches were markedly dilated; the left ventricle was judged greatly enlarged.

The venae cavae and coronary sinus opened normally to the right atrium. A large tear in the septum primum was seen, evidently produced by balloon atrial septostomy. The tricuspid valve was normal and the right ventricle was hypertrophied. The infundibular septum was displaced anteriorly and to the right of the ventricular septum, resulting in a malalignment infundibuloventricular type of ventricular septal defect. The subaortic infundibulum was not stenotic. The aortic arch was left-sided, its branches were normal, and no ductus arteriosus was present. Typical of D-transposition of the great arteries there was pulmonary-mitral fibrous continuity. The pulmonary annulus was only slightly stenotic. The pulmonary valve leaflets were severely distorted, myxomatous, and hypoplastic. Therefore, although present anatomically, they were virtually absent functionally.

Cases 2 and 3: Systemic venous return, right atrium, and tricuspid valve were normal. The infundibular septum was displaced rightward and anteriorly relatively to the ventricular septum, resulting in an infundibuloventricular type of ventricular septal defect, and the right ventricle was hypertrophied. The pulmonary annulus was stenotic and pulmonary leaflets were not identified. The main, right, and left pulmonary arteries were massively dilated. The pulmonary veins, left atrium, mitral valve, left ventricle, aortic valve, and coronary arteries were grossly unremarkable. The aortic arch was right-sided in Case 2 and left-sided in Case 3. A ductus arteriosus or ligamentum arteriosum was not found in either case.

Morphometric findings in the lung (Table II): *Lobation* of the lungs was normal in all 3 cases. *Lung volumes* (fixed, inflated, right and left) in Cases 1 and 2 were within normal limits when compared with controls (Table II), even though on opening the chest in Case 1, the right lung and left upper lobe appeared enlarged and the left lower lobe seemed smaller than normal. In Case 3, in both lungs, the inflated volumes were greatly increased.

Alveolar development was normal in Case 1, but in Case 2 alveolar number was less than in the control and in Case 3 alveolar size was increased (Table II).

The main, right, and left pulmonary arteries were very enlarged in all 3 cases. The right and left pulmonary arteries were 3 to 4 cm in diameter and where they crossed the main bronchi the latter were compressed

TABLE II Results of Morphometric Examination of Lung

	Lung Volume (ml)		Bronchial Generations, Left Lower Lobe	Alveoli/ cm^2	Total Alveolar Number $\times 10^6$	Arteries per 100 Alveoli	Artery Size (μm)			Arterial Wall Thickness (% External Diameter)						Extension of Muscle

AD = alveolar duct level; CHD + PH = congenital heart defect + pulmonary hypertension; m = % of arteries fully muscularized; p = % of arteries partially muscularized; RB = respiratory bronchiolus level; TB = terminal bronchiolus.
* Based on an assessment of right lung volume only. † lower limit of normal based on published data.

(Fig. 3). These pulmonary arteries outside the lung had histologic evidence of an increased number of elastic laminae. The number of elastic laminae was twice normal in Cases 1 and 2, but only mildly increased in Case 3 (Table III). In all 3 patients, the individual elastic laminae were thick, fragmented, and arranged haphazardly as well as concentrically around the vessel. In absolute terms the vessel wall was thicker than normal (0.7 mm), but relative to the external diameter of the vessel, the wall thickness was normal (wall thickness 2%).

The intrapulmonary arteries were abnormal in all 3 cases. In Case 1 no lobar branches could be identified. The segmental arteries seemed to arise directly from the right and left pulmonary arteries (Fig. 4). In Cases 2 and 3 short lobar arteries were identified. Rather than single segmental arteries, tufts of vessels arose in all 3 cases (Fig. 4 and 5). In Cases 1 and 3 each individual artery was similar in size and each was slightly larger than a branch of a normal segmental artery. However, in Case 2 the arteries were not uniform in size, some being larger than normal and others smaller. In this patient, some

TABLE III Number of Elastic Laminae of Preacinar Arteries

	Right Pulmonary Artery	Lobar Artery	Segmental Artery			Fragmentation	Thickening
			Origin	50%	75%		
Case 1 (4 days)	54	. . .	8	4	3	++	+
Case 2 (4 mo)	54	6	5	4	3	++	+
Case 3 (3 mo)	26	. . .	8	4	3	++	+
Control 1 (4 days)	21	10	8	7	4	. . .	. . .
Control 2 (4 mo)	21	14	8	7	4	. . .	. . .
CHD + PH (3 mo)	21	10	10	7	4	. . .	++

50%, 75% = distance from hilum to periphery; + = present; ++ = severe; CHD + PH = congenital heart defect + pulmonary hypertension.

of the vessels formed large loop anastomoses (Fig. 6, top). In each case the abnormal segmental arteries had few side branches. They continued toward the periphery with little change in size, entwining and compressing the bronchi they accompanied. The bronchi were distorted and flattened rather than reduced in size (Fig. 6, bottom). If the normal intrapulmonary arterial branching pattern resembles a birch tree, in these cases it is comparable to a weeping willow (Fig. 3 to 5). Although at the segmental level the total number of arteries was increased, at the periphery of the lung the number of arteries was virtually normal. Microscopically, the intrapulmonary arteries at the segmental level were of normal wall thickness but the elastic laminae were normal or slightly reduced in number, irregularly thickened, and fragmented (Fig. 7).

The intraacinar pulmonary arteries were mildly enlarged in all 3 cases, but their number in relation to the alveolar number was normal (Fig. 8, top). In all cases the wall thickness of the normally muscular arteries was appropriate or minimally increased. However, in Cases 1 and 3, there was abnormal extension of muscle into very small peripheral arteries at alveolar duct and wall levels, which normally are nonmuscular.

The *bronchi* were normal in structure and appropriately cartilagenous in all cases, despite their distorted appearance (Fig. 8, bottom). However, in Case 1 we documented a reduced number of bronchial genera-

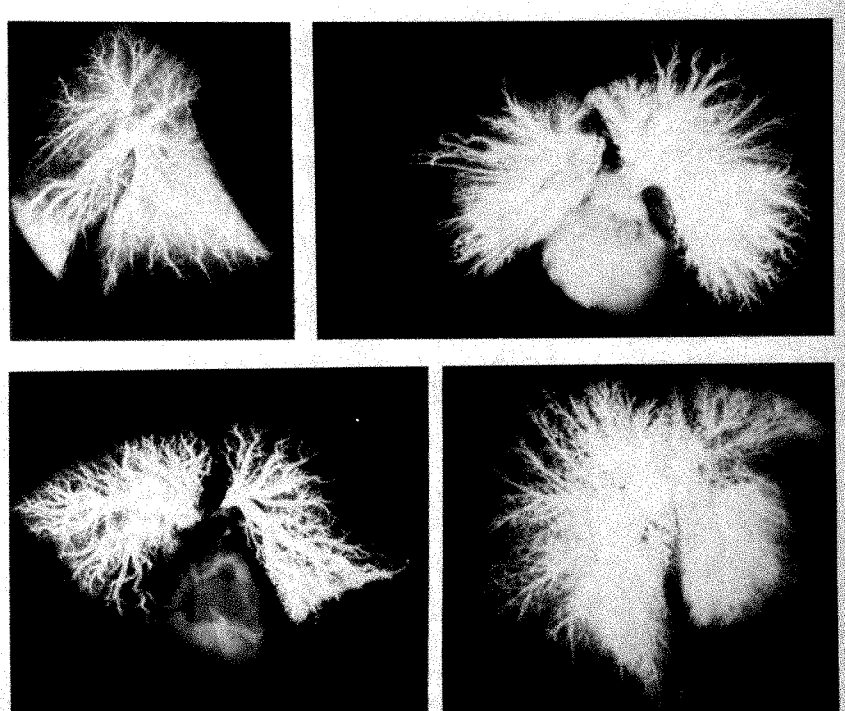

FIGURE 5. Top, postmortem arteriogram from a 4 month old control infant (**left**) and a 4 month old infant with the absent pulmonary valve syndrome (Case 2) (**right**); compared with Case 1, the vessels in Case 2 are less uniform in size and even form loops. **Bottom,** postmortem arteriogram from a 3 month old infant with double-outlet right ventricle and pulmonary hypertension (**left**) and a 3 month old infant with the absent pulmonary valve syndrome (Case 3) (**right**). In the former, the pulmonary arteries have a normal branching pattern but are dilated centrally, tortuous, and narrowed peripherally. In the latter, the pulmonary arteries are markedly increased in number from the hilum.

tions. The bronchial arteries appeared normal and there was no excessive connective tissue in the bronchovascular bundle.

The pulmonary veins were unremarkable in size, wall thickness, and number in all cases.

Comparison with postnatal pulmonary hypertension: The preceding pulmonary morphometric findings in these 3 patients with the absent pulmonary valve syndrome were compared with those of appropriate age-matched controls (Tables II and III) and also with those of a 3 month old infant with double-outlet right ventricle and postnatal pulmonary hypertension whose lungs were studied postmortem in the same manner. The findings in this infant were similar to those observed and previously reported in others with congenital heart defects and postnatal pulmonary hypertension, for example, ventricular septal defect.[24,25] The pulmonary arteries branched normally from the hilum to the periphery. The pulmonary arteries were dilated at the hilum, but narrower than normal peripherally (Fig. 5, bottom). Microscopically, the medial wall thickness was increased. The elastic laminae were normal in number but much thicker than normal and not fragmented (Fig. 7). The intraacinar arteries were smaller and fewer than normal. The wall thickness of arteries that normally are muscular was greatly increased and there was marked extension of medial muscle into peripheral arteries that normally are nonmuscular.

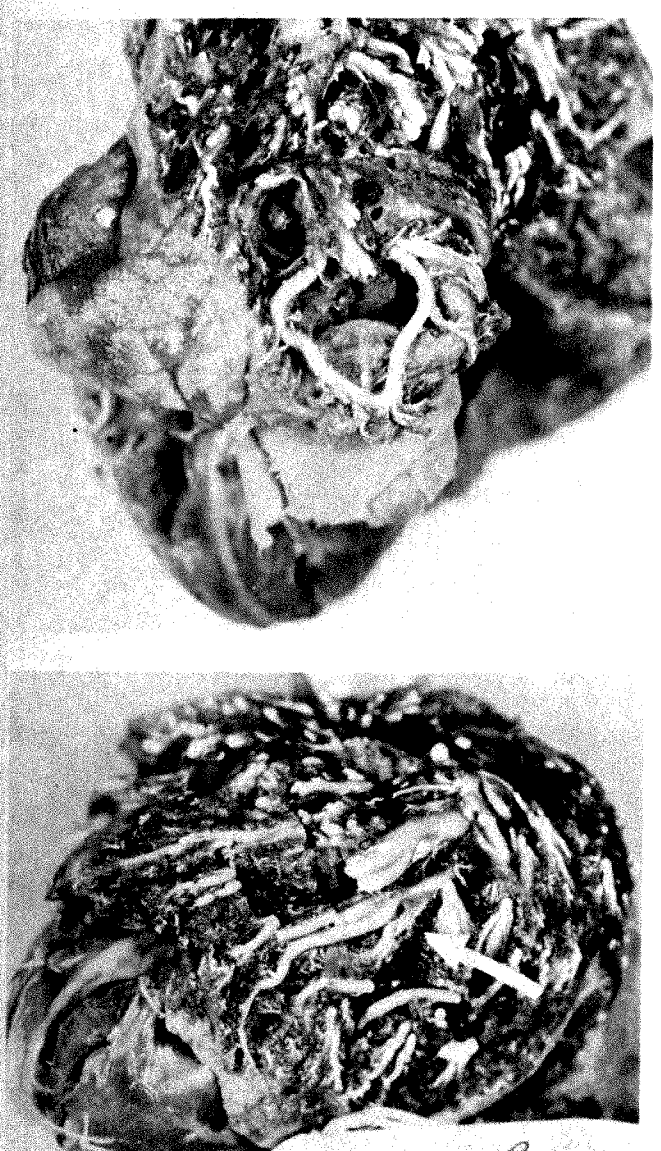

FIGURE 6. Top, dissected lung in Case 2 showing an arterial-to-arterial loop anastomosis, as seen on the postmortem arteriogram. **Bottom,** also in the dissection of the lung in Case 2, a bronchus was compressed between 2 dilated arteries (**arrow**).

Discussion

In this report we describe for the first time the abnormal and rather bizarre branching pattern of the hilar pulmonary arteries in patients with the absent pulmonary valve syndrome and document the first autopsy-proved case of the absent pulmonary valve syndrome in association with D-transposition of the great arteries.

In previous morphologic studies of the absent pulmonary valve syndrome a search was often made for an intrinsic abnormality in the wall of the dilated central pulmonary arteries (main, right, and left). Only some investigators found structural abnormalities, typically consisting of thickening and fragmentation of the elastic laminae and lack of ground substance within the media. In many of these cases, it is not clear whether the patients had, in addition to an absent pulmonary valve, absence of the ductus arteriosus. This combination seems to be associated with the most severe dilatation of the central pulmonary arteries. Our 3 patients all had this combination, and in all the walls of both the extra- and intrapulmonary arteries showed structural abnormalities but of different severity.

It is not known whether the abnormal branching pattern of the hilar pulmonary arteries that we observed in these 3 cases occurs in all patients with the absent pulmonary valve syndrome. Abnormal branching should be suspected in all but may well be found most often in those who also lack a ductus arteriosus. That abnormal pulmonary artery branching has not been reported previously is not surprising. The introduction of Short's technique[26] of postmortem pulmonary arteriography is relatively new and not a routine part of the postmortem examination in many hospitals. Also, cineangiocardiographic studies have in the past been concerned mainly with the central pulmonary arteries (main, right, and left), the ventricular septum, the infundibulum, and the pulmonary valve region. Little attention has been focused on the arteries within the lung. This was certainly true for the studies in these 3 patients. However, it should be possible to diagnose this anomaly of hilar branching by means of routine cineangiocardiography.

Embryology: At first it could be considered that intrapulmonary arteries appear to arise in bunches only because of incorporation of the higher generation vessels into the aneurysmally dilated central pulmonary arte-

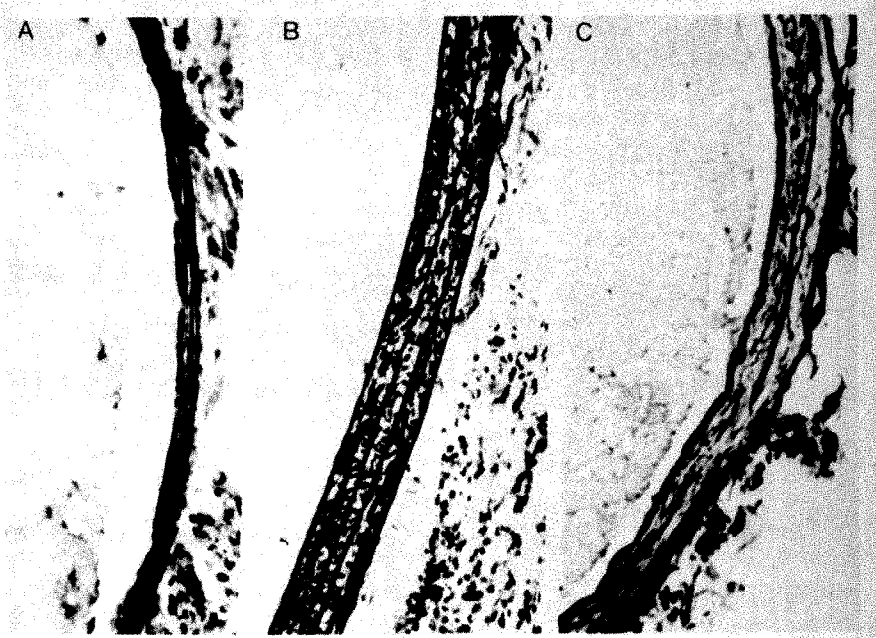

FIGURE 7. Photomicrographs of the muscular wall of the axial pulmonary artery of the right middle lobe, half way between the hilum and the periphery: **A,** from a 4 month old control infant; **B,** from the patient with double-outlet right ventricle; and **C,** from the patient with the absent pulmonary valve syndrome (Case 3). In **B** and **C** the wall is thicker than in **A.** The elastic laminae are very thick in **B** but are unevenly thick and fragmented in **C.** (Elastic Van-Gieson stain; original magnification ×40, reduced 25%).

ries; however, this does not explain the abnormal distal branching pattern.

From our knowledge of the timing of embryonic events, it is possible to suggest how the abnormal hilar branching pattern may arise. Alignment of the conotruncus (infundibulum and great arteries) with the ventricles takes place from the 30th to the 38th days of gestation.[27–29] If this process is disturbed, one result can be tetralogy of Fallot, as in Cases 2 and 3, and another result can be D-transposition of the great arteries, as in Case 1. Normally, it is just before this time that the definitive pulmonary arteries and ducti arteriosi are formed, from the 25th to the 29th days of gestation.[30,31] Therefore, we think that the characteristic abnormalities of the absent pulmonary valve syndrome probably appear between the 25th and 38th days of gestation. It may well be significant that during the 6th embryonic week, the segmental branches of the pulmonary arteries are the most actively growing pulmonary vascular structures.[31,32] We speculate that the increased pulmonary blood flow and pulse pressure associated with an absent pulmonary valve and an absent ductus arteriosus may stimulate their proliferation.

The question arises of why nonvascular structures such as the bronchi are also abnormal in the absent pulmonary valve syndrome. A single intrauterine insult at or before this critical time (25th to 38th days of gestation) could affect both the developing heart and lung, or the abnormal pulmonary arteries may compress the developing bronchi at the hilum and more peripherally (Fig. 3). Depending on the degree of compression, this extrinsic pressure could interfere with the ability of the bronchial tree to sprout new distal branches.

Why is absence of the ductus arteriosus so often associated with an absent pulmonary valve? The size of the ductus arteriosus appears to depend on the amount of right-to-left shunting through it in utero. Predictably, stenosis or atresia of the pulmonary outflow tract in tetralogy of Fallot is associated with a small or absent ductus arteriosus. Similarly, among patients with the absent pulmonary valve syndrome, those with the most severe pulmonary regurgitation (such as that due to absence of the pulmonary valve leaflets, and minimal pulmonary annular and infundibular stenosis) are most likely to lack a ductus.

Why are the pulmonary artery and its branches so large in the absent pulmonary valve syndrome, particularly in cases of absent ductus? The answer appears to be that, in late gestation, the pulmonary arteries must contain per unit time the right ventricular portion of the venous return, the flow that would ordinarily have been shunted through the ductus to the aorta, and the regurgitant fraction necessitated by the pulmonary regurgitation. The histologic abnormalities of the pulmonary arteries may well be secondary to this disturbed intrauterine hemodynamic function, in particular the extreme excursions between systolic distention and diastolic collapse.

Postnatal changes: Although the reduced number of bronchial generations in Case 1 (Table II) suggests an intrauterine insult, the reduced number of alveoli in Case 2 (Table II) could reflect a postnatal disturbance. The normal number of huge alveoli in Case 3 (Table II) most likely indicates a postnatal abnormality, probably secondary to prolonged ventilator therapy.

The 2 respirator-dependent patients were the ones in whom we observed structural changes in the peripheral pulmonary arteries similar to those associated with severe chronic hypoxia both clinically[33] and experimentally,[34] that is, extension of muscle into normally nonmuscular arteries. It seems likely, particularly in the infant who died at 3 months (Case 3), that these occurred postnatally. The patient who died at 4 days had D-transposition of the great arteries and ventricular septal defect; therefore, the excessively high pulmonary blood flow may also have contributed to the structural

changes, hence their early appearance.

Surgical implications: The 3 patients discussed in this report all had respiratory difficulties from birth and represent the group of patients with absent pulmonary valve that is most severely affected.[10] At the other end of the spectrum are patients with few if any cardiorespiratory symptoms who undergo elective cardiac surgery later in childhood.[35–37] For infants with severe symptoms, various surgical procedures have been proposed. Litwin et al.[38] in 1973 recommended that surgery be carried out in stages. The 1st stage, performed during infancy, involves relief of compression of one of the mainstem bronchi, usually by interposing a conduit between the main pulmonary artery and the distal right pulmonary artery. At the 2nd stage, performed later in childhood, the initial conduit is replaced by a larger one and the intracardiac defect is repaired.

More recently, good results were reported[39] by relieving the bronchial compression and correcting the intracardiac defect in a 1-stage procedure. The 1 step surgical technique has the distinct advantage of leaving the patient with normal rather than increased pulmonary blood flow. The result should be less distention of the intrapulmonary arteries, thereby lessening compression of hilar and intrapulmonary bronchi. The inclusion of some sort of pulmonary valve (such as a dura mater monocusp) may be desirable in theory, but in practice needs further assessment. Bronchodilator therapy may be beneficial in infants with exceedingly severe compression of the intrapulmonary bronchi. However, in some infants the severity of the intrapulmonary bronchial compression perhaps precludes a successful result from either surgical or medical therapy.

Once having described abnormalities in the branching pattern of the hilar segmental arteries on the basis of postmortem angiography, it now remains to diagnose these abnormalities in routine cineangiocardiograms obtained at cardiac catheterization. In the future it will be useful to correlate the severity of the vascular abnormalities with the degree of functional impairment judged by criteria such as the need for assisted ventilation, recurrence of pulmonary infections, or relative lack of clinical disturbance. It will be important also to correlate these abnormal hilar branching patterns with responses to the various forms of medical and surgical therapy.

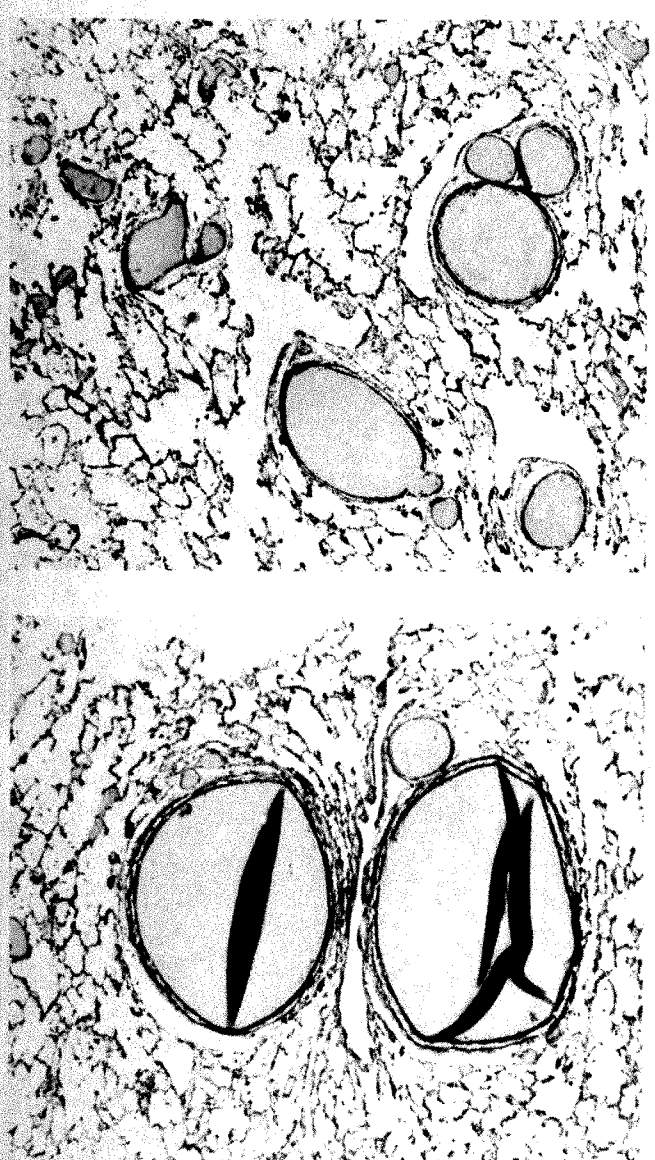

FIGURE 8. Top, photomicrograph of the intraacinar arteries in Case 2 showing slight increase in size but a normal number. Muscularity is appropriate in terms of both degree of extension into peripheral arteries and wall thickness. (Elastic Van-Gieson stain; original magnification ×100, reduced 29%). **Bottom,** photomicrograph of an intrapulmonary bronchus compressed between dilated preacinar arteries. (Elastic Van-Gieson stain; original magnification ×100, reduced 35%).

Acknowledgment

We thank Kenneth E. Fellows, MD, for helping interpret the cineangiographic studies and Alexander S. Nadas, MD, for his advice and encouragement. We appreciate the technical assistance of Vera Daniels, Natalie Daniels, and Bernice Oliver; the secretarial assistance of Linda Washington, Carolee Tremblay, Terrie Waters, and Katherine Belansus; and the artistic contributions of Jean Kanski, Dominic Screnci, and Perley Brown.

Two-Dimensional Echocardiographic Identification of Pulmonary Artery Branch Stenosis

DAVID D. TINKER, MD, NAVIN C. NANDA, MD, J. PETER HARRIS, MD, and JAMES A. MANNING, MD

Pulmonary artery branch stenosis is a not uncommon congenital lesion, noted in approximately 4% of children at the time of cardiac catheterization. Real-time 2-dimensional echocardiography was used to examine 10 patients with angiographically documented pulmonary branch stenosis. Five cases of pulmonary artery branch narrowing were identified by echocardiography without prior knowledge of angiographic findings. In 5 other patients whose angiographic results were known, the narrowings were identified in 4 of 5 cases. These results demonstrate the feasibility of evaluating pulmonary branch stenosis with the nonionizing, noninvasive method of 2-dimensional echocardiography.

Pulmonary artery branch stenosis is a congenital cardiac lesion that may occur alone or in combination with other cardiac anomalies, most commonly pulmonic valve stenosis, atrial and ventricular septal defects, and patent ductus arteriosus. Also, pulmonary artery stenosis is associated with the congenital syndrome of supravalvular aortic stenosis (Williams syndrome). Usually no cause of pulmonary artery branch stenosis is identified, but an association with maternal rubella syndrome has been recognized.[1] The diagnosis may be suspected clinically on the basis of a systolic murmur with wide radiation, but requires cardiac catheterization and angiography for confirmation. In this study we report the detection of these lesions using real-time 2-dimensional echocardiography, an application of echocardiography that has not previously been described to our knowledge.

Methods

Study patients: The study group consisted of 10 patients, aged 5 to 25 years (Table I). Five of the patients (Cases 1 to 5) were studied either before angiography or without knowledge of angiographic results. The remaining 5 patients (Cases 6 to 10) were known to have angiographically documented peripheral pulmonary artery stenosis before echocardiographic study. Associated lesions included atrial septal defect in 2 patients, 1 of whom also had pulmonary valve stenosis; tetralogy of Fallot in 2 patients; and tricuspid atresia, single ventricle, and pulmonary atresia each in 1 patient. Three patients had no associated cardiac anomalies. Pressure data were available in 4 patients (Cases 6 to 9), and the peak systolic gradient across the stenosed pulmonary artery ranged from 19 to 81 mm Hg. In the remaining patients the pressures were not obtained because of severe stenosis or atresia (Cases 1 and 4), stenosis too distal (Case 10), or other anatomic anomalies (Cases 2, 3, and 5). A second group of 10 pediatric patients with angiographically documented normal pulmonary arteries was studied by echocardiography without knowledge of angiographic results.

Echocardiography: All patients were examined using real-time 2-dimensional echocardiography with a 90°, 3 MHz mechanical sector scanner (Advanced Technology Laboratories). All examinations were performed using parasternal, subcostal, and suprasternal/supraclavicular techniques.

Parasternal technique: The pulmonary valve is identified in the standard manner[2] and then the transducer is angled further to the left to attempt to visualize the main pulmonary

TABLE I Pulmonary Artery Findings

Case	Age (yr)	Echocardiogram	Angiogram	Associated Lesions
1	25	Miniscule RPA	Same as echo	Tricuspid atresia, PDA
2	7	Tubular narrowing of RPA, narrowed proximal PA	Same as echo	Pulmonary atresia, hypoplastic RV s/p Waterston shunt
3	11	Small RPA and MPA	Same as echo	Single ventricle s/p Waterston shunt
4	21	Absent RPA	Same as echo	Tetralogy of Fallot
5	11	Narrowed MPA and RPA	Same as echo	Tetralogy of Fallot s/p Blalock procedure
6	8	Narrowed RPA with small superior branch; narrowed LPA at origin	Same as echo	None
7	20	Narrowed RPA with post-stenotic dilatation; dilated MPA	Same as echo; also stenosis of LPA at origin of lingular branch	None
8	5	Narrowed LPA, dilated MPA	Same as echo	ASD
9	17	Narrowed distal RPA; dilated MPA with increased pulsations	Same as echo; narrowed LPA distally; multiple stenoses of 2° and 3° branches of RPA and LPA	Pulmonary valve stenosis; ASD
10	10	No abnormality seen	Narrowed RPA after superior branch take-off; superior branch ends in stump	None

ASD = atrial septal defect; Echo = echocardiogram; LPA = left pulmonary artery; MPA = pulmonary artery; PDA = patent ductus arteriosus; RPA = right pulmonary artery; RV = right ventricle; s/p = status post; VSD = ventricular septal defect.

trunk. In some patients minimal adjustment of the transducer brings the proximal portions of the right and left pulmonary artery into the echo plane (Fig. 1).

Subcostal technique: The pulmonary trunk and proximal portions of the primary branches are imaged in some patients, especially children, by placing the transducer in the subcostal area and directing it superiorly (Fig. 2).

Suprasternal/supraclavicular technique: The transducer is placed in the suprasternal notch and angled inferiorly and somewhat to the right to visualize a large segment of the right pulmonary artery (Fig. 3). In some patients the proximal portion of the superior branch of the right pulmonary artery is also seen before the vessel is lost within lung parenchyma. The transducer can then be directed somewhat posteriorly to visualize the left pulmonary artery. Although the left pulmonary artery is generally less easily visualized than the right pulmonary artery, the first portion of its branches is occasionally seen (Fig. 4).

Some of the pulmonary artery anatomy viewed in the foregoing approaches has been previously described and validated.[3,4] In our laboratory echocardiographic contrast studies utilizing injections of 5% dextrose have been performed during cardiac catheterization procedures in patients without pulmonary branch stenosis to validate pulmonary artery anatomy (Fig. 2 and 3).

Normal 2-dimensional echocardiographic dimensions have not been established for the pulmonary vessels. For the purposes of the study we considered stenosis present if (1) a vessel abruptly narrowed by 50% or more of its adjacent diameter, and (2) the right pulmonary artery was 25% or less of the transverse aortic arch diameter. The main pulmonary artery was considered dilated if its diameter measured in the precordial view was 1.5 or more times the diameter of the aortic root.

Results

Pulmonary artery echocardiographic findings (Table I, Fig. 5 to 7): The echocardiographic diagnosis of pulmonary branch artery stenosis was made prospectively in 5 patients (Cases 1 to 5) who were studied as part of routine noninvasive evaluation or follow-up of complex cardiac anomalies. In each case, cardiac angiograms confirmed the suspected stenosis. The remaining 5 patients (Cases 6 to 10) were studied knowing that pulmonary artery stenosis was present. In general, these patients had fewer associated cardiac anomalies, and 3 were being followed up only for isolated pulmonary branch stenosis. In all but 1 (Case 10), stenotic regions were identified by echocardiography,

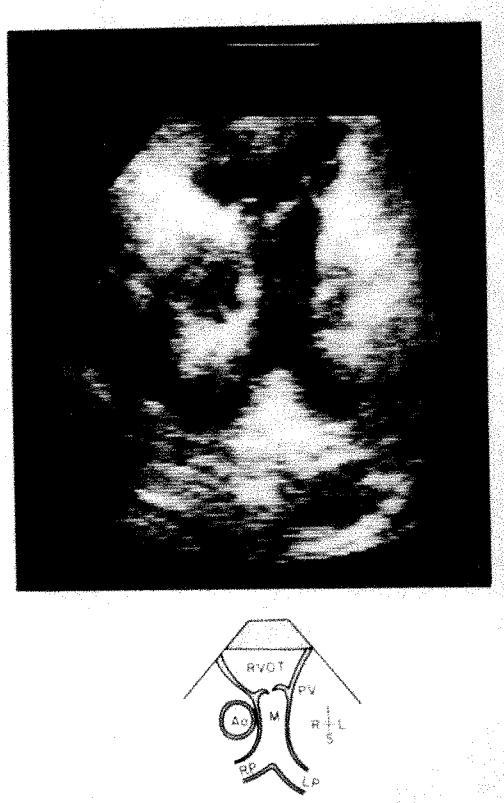

FIGURE 1. Pulmonary trunk and primary branches from parasternal transducer position. Diagrammed below are the right ventricular outflow tract (RVOT), pulmonary valve (PV), main pulmonary artery (M), right pulmonary artery (RP), and left pulmonary artery (LP). AO = aorta; I = inferior; L = left; R = right; S = superior.

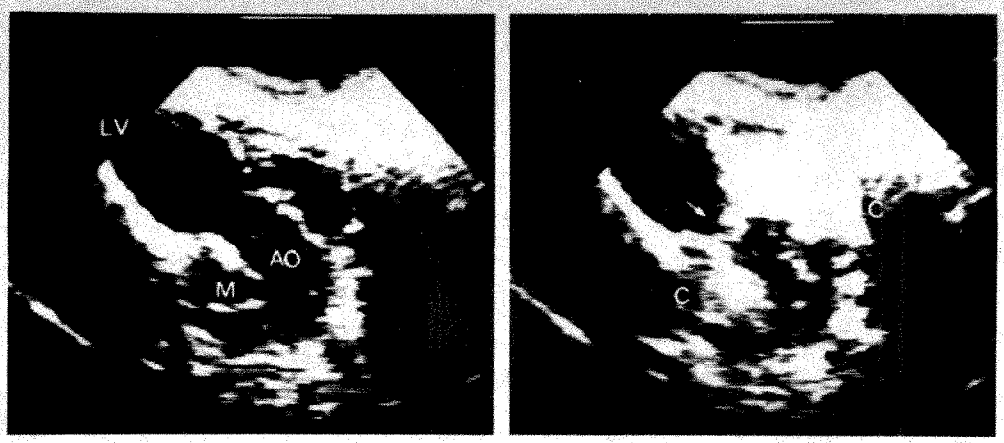

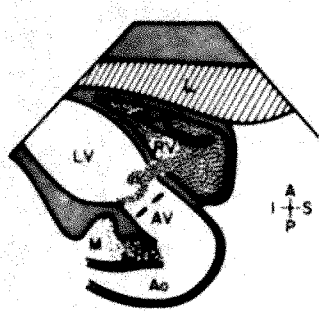

FIGURE 2. Pulmonary artery visualization from subcostal transducer position. **Top left,** the main pulmonary artery (M) and the proximal portion of its right branch are visualized in a patient with a ventricular septal defect and a right-to-left shunt. **Top right,** contrast injections into the inferior vena cava result in contrast filling (C) of the right ventricle (RV) and main and right pulmonary arteries. Some contrast medium (**arrow**) passes into the left ventricle (LV) through the ventricular septal defect. In the diagram at **left,** A = anterior; Ao = aorta; AV = aortic valve; I = inferior; L = liver; P = posterior; S = superior.

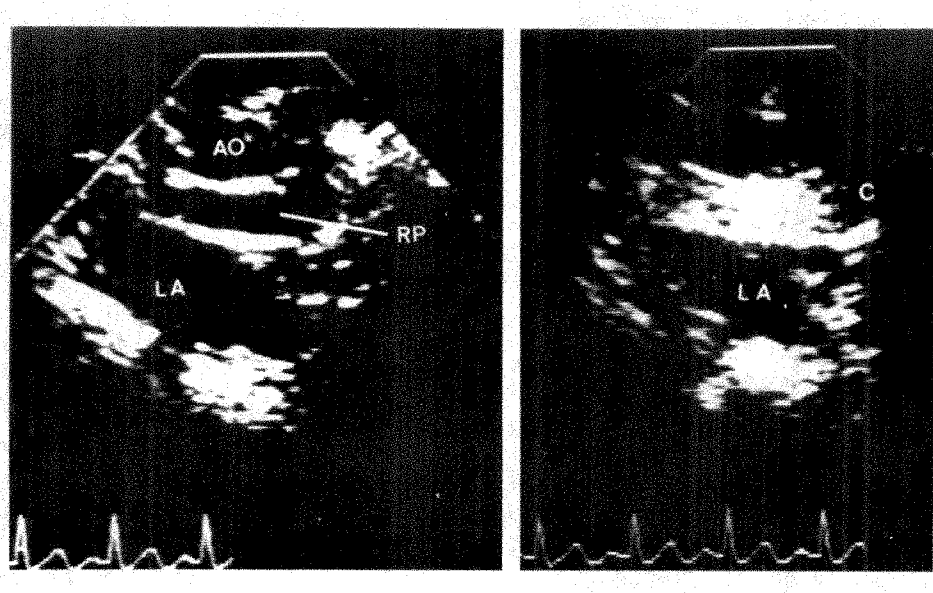

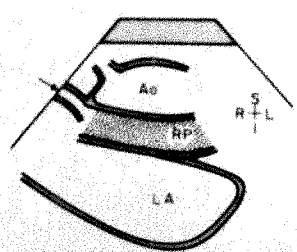

FIGURE 3. Right pulmonary artery from suprasternal transducer position. **Top left,** a large segment of the right pulmonary artery (RP) is seen between the transverse aorta (AO) and left atrium (LA). Note also the proximal portion of the superior branch of the right pulmonary artery (**arrow**). **Top right,** contrast medium (C) injected from the inferior vena cava fills the right pulmonary artery. At **left,** I = inferior; L = left; R = right; S = superior.

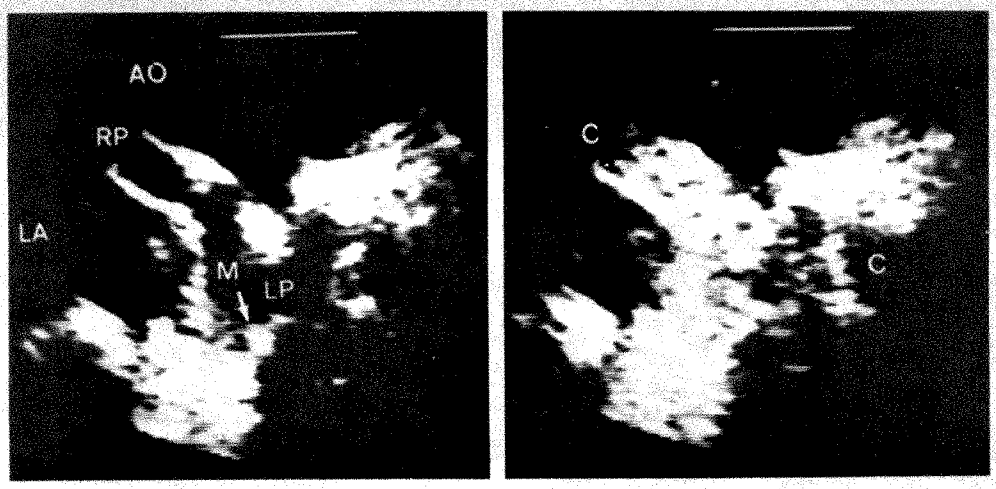

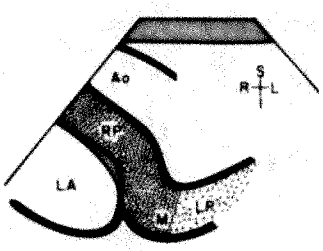

FIGURE 4. Pulmonary arteries from the suprasternal transducer position. The transducer is angled further leftward and somewhat posteriorly compared with the position in Figure 3. **Top left,** before injection of contrast medium the right pulmonary artery (RP) is seen located between aorta (AO) and left atrium. The anterior aortic wall is not visualized because of reduced gain in the proximal echo field used to optimize pulmonary artery recordings. The right branch is contiguous with the main pulmonary trunk (M) and left branch (LP). **Top right,** contrast medium (C) injected in the inferior vena cava appeared first in the main pulmonary artery and then quickly filled the branches. At **left,** I = inferior; L = left; R = right; S = superior.

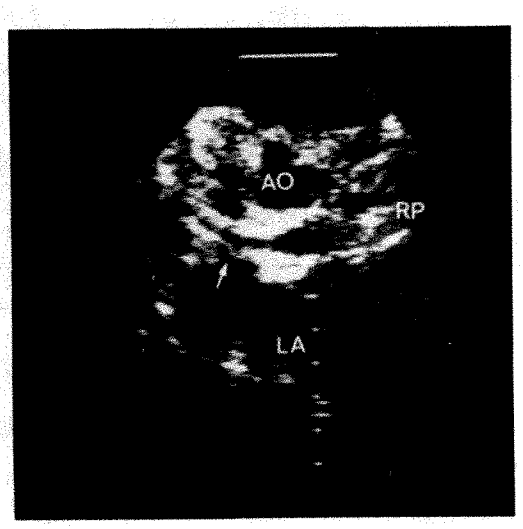

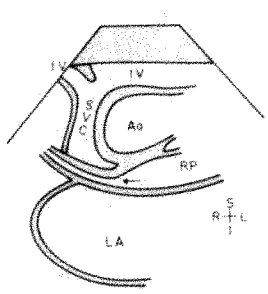

FIGURE 5. Case 2, suprasternal transducer position. The proximal right pulmonary artery (RP) is of normal caliber, but tapers distally to a segment of tubular narrowing (**arrow**). Ao = aorta; I = inferior; IV = innominate vein; L = left; LA = left atrium; R = right; S = superior; SVC = superior vena cava.

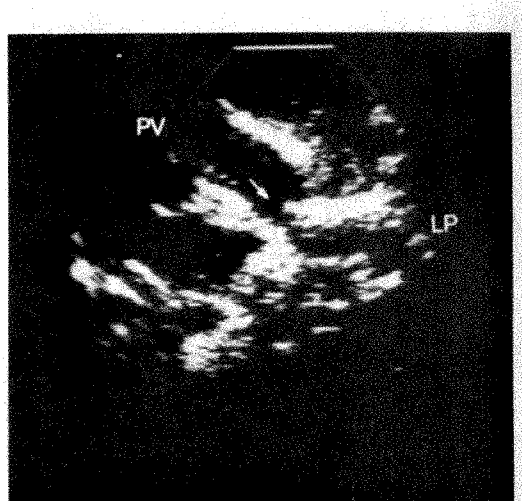

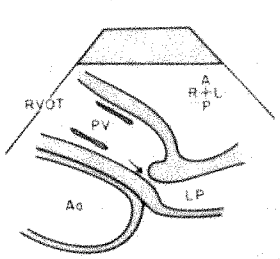

FIGURE 6. Case 6, parasternal transducer position. The left pulmonary artery (LP) is shown with narrowing at its take-off point from the main trunk (**arrow**). The right branch is not seen in this plane. A = anterior; Ao = aorta; L = left; P = posterior; PV = pulmonary valve; R = right; RVOT = right ventricular outflow tract.

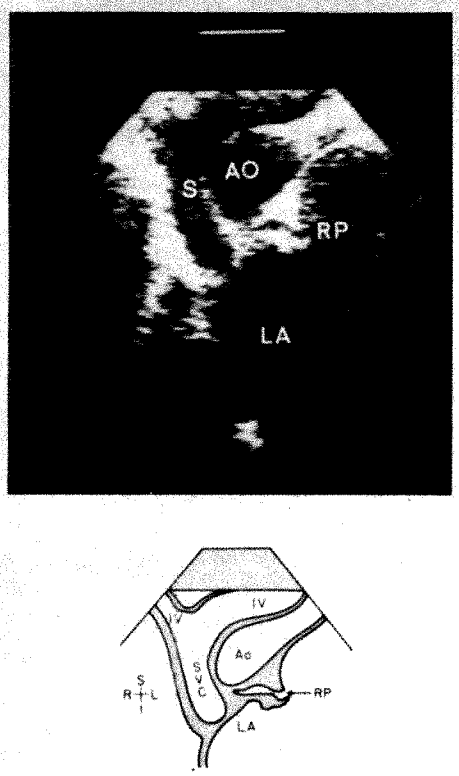

FIGURE 7. Case 1. Pulmonary artery branch stenosis associated with tricuspid atresia. The narrow space between the aorta (AO) and left atrium (LA) represents a miniscule right pulmonary artery (RP) seen from the suprasternal approach. I = inferior; IV = innominate vein; L = left; R = right; S = superior; S (SVC in diagram) = superior vena cava.

which corresponded closely to the angiographic findings. Although all transducer approaches were useful in recognizing the pulmonary arteries, the main pulmonary artery was most consistently imaged from the parasternal position, and the right and left pulmonary arteries with their proximal branches were seen best from the suprasternal/supraclavicular approach. The main pulmonary artery and proximal portions of its two branches were visualized in all patients utilizing multiple transducer positions.

Correlation with angiographic findings: In most cases the echocardiographic findings correlated well with those shown in the angiogram, especially when the stenosis was proximal. We failed to see stenosis of the lingular branch of the left pulmonary artery in 1 patient (Case 7), bilateral multiple narrowings of secondary and tertiary branches of the pulmonary artery in 1 patient (Case 9), and narrowing of the right pulmonary artery distal to the origin of the superior branch in a third patient (Case 10). The interesting finding of a dilated main pulmonary artery with prominent pulsations was noted in Patient 9 with the multiple stenoses of the secondary and tertiary pulmonary branches. In 2 patients (Cases 1 and 4) the right pulmonary artery was miniscule or absent, and these findings were confirmed by angiography in both. In the 10 patients with angiographically normal pulmonary arteries, no evidence of narrowing in the pulmonary vascular tree was detected by echocardiography.

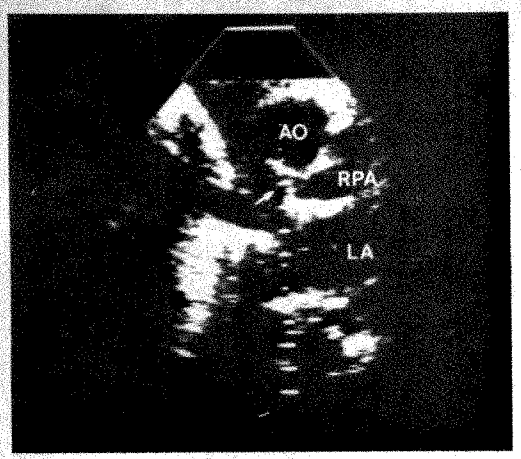
Discussion

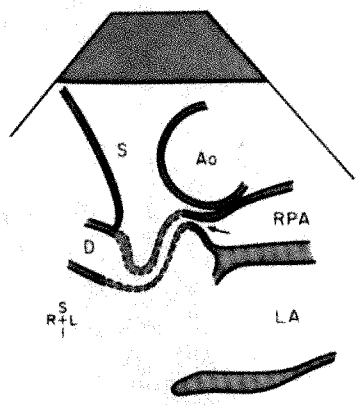
Clinical features: Stenosis of the pulmonary artery has been recognized with increasing frequency since cardiac catheterization and angiography became available. Several classifications have been suggested based on anatomic location (trunk, right or left branches, peripheral branches) and type of stenosis (tubular, discrete).[5,6] It is a relatively common congenital lesion, being reported in 4% of children undergoing catheterization.[7] Approximately half of the patients with pulmonary artery stenosis have associated cardiac lesions, most commonly pulmonic valve stenosis, atrial septal defect, ventricular septal defect, patent ductus arteriosus, or tetralogy of Fallot.[8]

A systolic murmur, typically grade 2/6 to 3/6 with wide radiation to the back and axillae, is almost always present but can be obscured by other cardiac anomalies.[9] The natural history of isolated pulmonary artery stenosis is generally benign,[10] but complications including pulmonary hypertension, right ventricular failure, pulmonary artery thrombosis, and poststenotic aneurysmal dilatation with rupture and hemoptysis have been reported.[8,11] A number of investigators have pointed out the importance of defining pulmonary artery anatomy before surgical repair of complicated cardiac anomalies such as tetralogy of Fallot. Unrecognized pulmonary branch stenosis has led to poor postoperative results because of unrelieved pulmonary hypertension.[12] Surgical correction of pulmonary artery stenosis has been described and is feasible if the obstruction occurs proximally.[13]

Echocardiographic diagnosis: This is the first study demonstrating the feasibility of diagnosing pulmonary artery branch stenosis utilizing real-time 2-dimensional echocardiography. Previously, confirmation of clinically suspected pulmonary artery stenosis required cardiac catheterization and angiography. Both M-mode and 2-dimensional echocardiography have previously been applied to the diagnosis of Williams syndrome. One report describes M-mode identification of supravalvular aortic stenosis in a patient also having multiple pulmonary branch stenosis, but no attempt was made to visualize the pulmonary stenoses.[14] A recent report[15] described the 2-dimensional echocardiographic features of aortic stenosis in a patient with Williams syndrome, but pulmonary artery stenosis was angiographically absent.

In our series, abnormalities of the pulmonary artery were detected by echocardiography prospectively in 5 patients and 4 of 5 patients with known pulmonary branch stenosis. The lesions which were missed occurred peripherally in close vicinity to the lung, which may have obscured the more distal pulmonary branches. This constitutes the major limitation of the technique since only the main pulmonary artery, right pulmonary artery, left pulmonary artery, and occasionally their first branches can be viewed before being obscured by lung





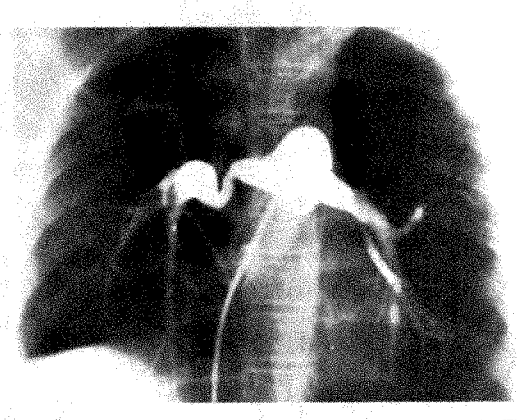


FIGURE 8. Case 7. **Top and middle,** suprasternal approach. The right pulmonary artery (RPA) lying between aorta (AO) and left atrium (LA) abruptly narrows (**arrow**). It is then lost as it courses out of the 2-dimensional echo plane. Where it reappears distally, the lumen is wide without evidence of stenosis. The schematic drawing shows the tortuous segment of the right pulmonary artery (**dashed line**) which was not visualized on the echocardiogram and which connects the area of stenosis (**arrow**) and the poststenotic dilatation (D). (S = superior vena cava. Orientation: I = inferior, L = left, R = right, S = superior). **Bottom,** the pulmonary artery angiogram shows narrowing of the right pulmonary artery corresponding to the echocardiogram. Poststenotic dilatation seen on the angiogram corresponds to the area of distal luminal widening (D) seen on echocardiography. This illustrates a limitation of 2-dimensional echocardiography. The technique can only view, at any given time, structures or portions of structures located in the same echocardiographic plane.

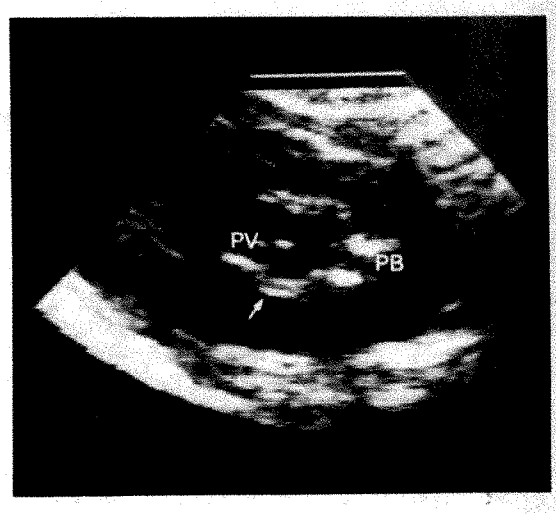
parenchyma. Tertiary branch stenosis cannot be visualized by echocardiography.

The pulmonary valve and main pulmonary artery are best seen using the parasternal approach, and were visualized in all of our patients in this manner. The right and left branches can be seen in their proximal portions using either the precordial or subcostal view, but are best seen from the suprasternal approach. The left pulmonary artery is often less easily seen than the right pulmonary artery since it has a shorter course before reaching the lung hilum. The bifurcation of the main pulmonary artery into right and left branches is often well imaged from the parasternal position, but from the suprasternal view it may be difficult to distinguish the main pulmonary artery from the beginning of its branches. The angled 2-dimensional transducer head used in this study is well suited for suprasternal examination, but transducer size may be a limitation in smaller patients.

Clinical applications: This new application of 2-dimensional echocardiography is of clinical value in noninvasively confirming the diagnosis in patients who are suspected to have isolated pulmonary artery branch



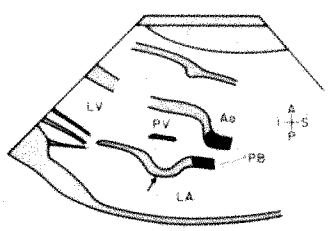


FIGURE 9. Pulmonary artery banding. Parasternal transducer position. This patient with transposition of the great vessels and ventricular septal defect has a pulmonary artery band (PB) surgically placed to narrow the pulmonary artery trunk and limit pulmonary blood flow. Note the bright echoes from the synthetic banding material, which help differentiate iatrogenic narrowing from congenital stenosis. The **arrow** indicates dilatation of the posterior pulmonic sinus which occurred secondary to the banding procedure. A = anterior; AO = aorta; I = inferior; LA = left atrium; LV = left ventricle; P = posterior; PV = pulmonary valve; S = superior.

stenosis, or in patients with complex cardiac lesions undergoing surgery in whom failure to recognize associated branch artery stenosis may lead to poor postoperative results. The technique may also be used to examine patients with maternal rubella syndrome, Williams syndrome, or other conditions which predispose to pulmonary branch stenosis. Although our series is too small to comment on the specificity or sensitivity of the test, we were able to prospectively identify five cases of pulmonary artery branch stenosis by echocardiography. We now routinely look at pulmonary artery structure during echocardiographic examinations. A review of 10 sequential pediatric patients with normal pulmonary artery angiograms who underwent echocardiography blinded to angiographic results showed no echocardiographic false-positive diagnoses for pulmonary artery stenosis.

Technical considerations: Some pitfalls and problems in the diagnosis of branch pulmonary artery stenosis by echocardiography need be considered. A physiologic peripheral pulmonary branch stenosis may be seen in neonates, usually preterm infants, in whom the branch arteries are considerably smaller in diameter relative to the diameter of the main pulmonary artery than they are several months later. In neonates, the diagnosis of true structural bilateral stenosis should be made with caution only after serial examinations. In our series the youngest patient was 5 years old, so this problem did not arise. Technical problems include difficulty in accurate assessment of vessel diameter. The transducer should be moved and angled in multiple directions to obtain maximal vessel diameter. The vessel size may be underestimated if the echo plane does not transect the middle of the vessel when viewed in long axis. Vessel tortuosity may prevent visualization of its full length in a given 2-dimensional plane (Fig. 8). The echo plane is equivalent to a thin cross-sectional slice through the heart and great vessels, and multiple 2-dimensional views may be required to piece together an overall picture of vessel anatomy. Narrowing of the main pulmonary artery by surgical banding may be confused with congenital stenosis. However, the synthetic banding material produces dense bright echoes in the region of the banded area, and this finding is helpful in differentiating it from congenital pulmonary artery stenosis (Fig. 9). As with other echocardiographic examinations, it is important to utilize mutliple depth and gain control settings to obtain optimal images of the pulmonary arteries.

Conclusion: Our findings demonstrate the capability of detecting branch pulmonary artery stenosis using real-time 2-dimensional echocardiography. The parasternal and subcostal views are useful for imaging the main pulmonary artery. With the suprasternal/supraclavicular approach, longer segments of the right and left pulmonary arteries as well as the proximal secondary branches can be visualized. More peripheral branches cannot be seen with echocardiography. These results are preliminary but suggest that this nonionizing, noninvasive technique deserves further prospective investigation in the evaluation of pulmonary branch stenosis.

Acknowledgment

We are grateful to Paul N. Yu, MD, Chief of Cardiology, for reviewing the manuscript.

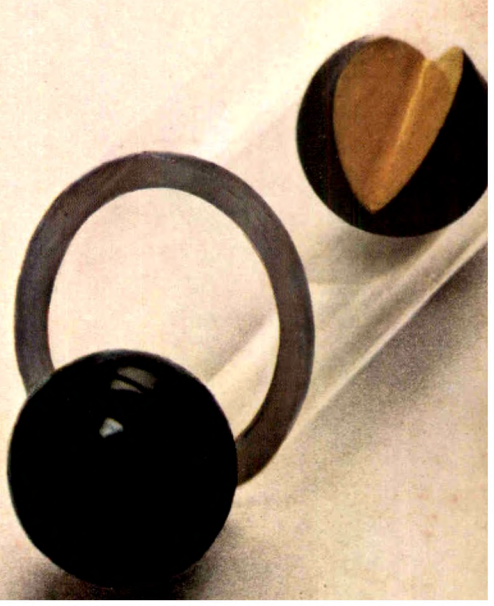
FROM PARKE-DAVIS RESEARCH:

NOW— A LIPID REGULATOR MAY COME CLOSER TO THE GOAL OF THERAPY FOR CERTAIN DYSLIPIDEMIAS.



INTRODUCING LOPID®

(gemfibrozil) 300-mg capsules

FAVORABLY REGULATES THE BALANCE OF LIPID FRACTIONS IN CERTAIN DYSLIPIDEMIAS.

For treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond to diet.

1/ LOPID LOWERS ELEVATED SERUM LEVELS of THE VLDL FRACTION (very-low-density lipoproteins implicated in dyslipidemia).

Studies in humans also show LOPID inhibits peripheral lipolysis and decreases hepatic extraction of free fatty acids—thereby reducing hepatic triglyceride production.

LOPID also inhibits synthesis of VLDL carrier apoproteins, thereby decreasing VLDL production.

2/ LOPID MAY ALSO RAISE SERUM LEVELS of THE HDL FRACTION (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion).

Studies in animals suggest LOPID may also accelerate hepatic turnover and removal of cholesterol—thereby increasing cholesterol excretion.

PARKE-DAVIS

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO
		Total	VLDL	LDL	HDL	HDL Cholesterol / Total Cholesterol
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure.

Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings)

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis — LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants — Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. *Initial Therapy* — Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. *Continued Therapy* — Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. *Seasonal Variation of Lipid Levels* — LOPID is not expected to alter seasonal variations of higher serum lipid values in midwinter and late summer or the lower values in fall and spring.

4. *Impairment of Fertility* — Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. *Pregnancy Category B* — Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 5.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. *Nursing Mothers* — Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. *Hematologic Changes* — Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. *Liver Function* — Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. *Cardiac Arrhythmias* — Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. *Use in Children* — Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

EXPERIMENTAL STUDIES

Ventricular Performance and Biochemical Alteration of Regional Ischemic Myocardium After Reperfusion in the Pig

MARVIN L. MURPHY, MD, CHUN FU PENG, PhD, JAMES J. KANE, Jr., MD, and KARL D. STRAUB, MD, PhD

Reperfusion of acutely ischemic myocardium may cause profound alterations in left ventricular wall performance and metabolism. This study evaluates regional left ventricular wall thickness, analyzes metabolic and biochemical alterations, and examines tissue hemorrhage during 15, 30, and 120 minutes of myocardial ischemia, each followed by 120 minutes of reperfusion. Reperfusion after 15 minutes of ischemia showed nearly normal ventricular wall thickening and motion, intact metabolic and biochemical function, and no tissue hemorrhage. However, reperfusion after 30 and 120 minutes of ischemia was associated with ventricular wall thickening and failure to resume systolic and diastolic wall motion. Furthermore, adverse metabolic and biochemical alterations and reperfusion zone hemorrhaging increased proportionally with the duration of ischemia. These findings suggest critical myocardial damage occurring between 15 and 30 minutes of ischemia in an animal model without preexisting coronary collateral circulation. The observed metabolic and biochemical changes are consistent with irreversible cell membrane defects, allowing calcium ion accumulation and thus adversely affecting diastolic relaxation and systolic thickening.

Saphenous vein bypass grafting is accepted therapy for chronic, stable angina unresponsive to medical treatment, but its use in acute myocardial infarction remains controversial. In addition, current interest in the use of thrombolytic agents in acute infarction focuses renewed attention on the functional and metabolic aspects of reperfusion of ischemic myocardium.[1–5] Experimental studies show that reperfusion of acutely ischemic myocardium may be deleterious,[6] resulting in myocardial necrosis[7] as well as striking changes in left ventricular wall thickness and contractility.[8,9] The mechanism of reperfusion damage is not well understood and may relate to the duration and degree of ischemia. Changes in regional blood flow and reactive hyperemia have been suggested as an explanation for injury.[10,11] Other observers[12] note considerable edema in reperfused tissue and suggest that both edema and loss of cell volume regulation play an important role in the development of irreversible ischemic injury. A recent extensive review[13,14] of factors affecting infarct size emphasizes the complexity of data interpretation in human and experimental reports of ischemia and reperfusion.

The purpose of this study was (1) to define the magnitude and time course of changes in left ventricular performance by evaluating wall thickening and thinning, as related to varying periods of coronary occlusion followed by a standard reperfusion time, and (2) to relate changes in left ventricular wall motion to the accompanying metabolic state of the myocardium.

Methods

Experimental protocol: The pig was chosen as the experimental model because its major coronary distribution, collateral circulation, and conduction system blood supply is identical to that of man.[15–17] Twenty-three mature farm pigs

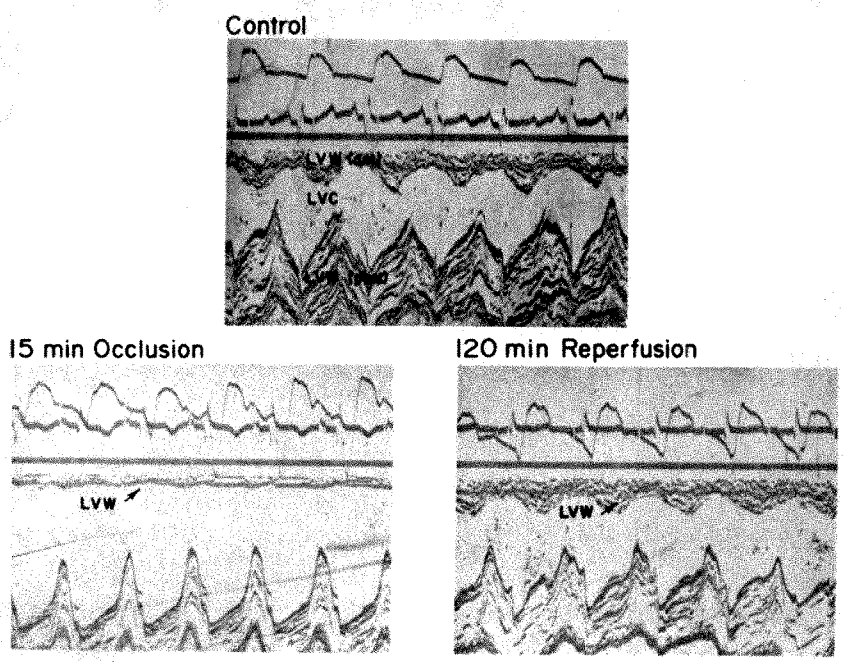

FIGURE 1. Echocardiographic left ventricular wall thickness. **Top panel,** control echocardiogram recorded before coronary occlusion. The anterior (ant) left ventricular wall (LVW) thickens during systole followed by diastolic thinning. **Lower left,** recording performed over the same area of the left ventricle after 15 minutes of coronary occlusion. There is loss of systolic thickening and thinning of the anterior wall. **Lower right,** after 120 minutes of reperfusion, there is near-normal left ventricle thickening and thinning. LVC = left ventricular chamber; LVW = left ventricular wall; post = posterior.

weighing 30 to 55 kg were anesthetized with 6% phenobarbital sodium administered intravenously after an 18 hour fast. Tracheostomy was performed and respiration maintained with a Harvard pump respirator, using room air supplemented by oxygen and adjusted to maintain an arterial PaO_2 greater than 100 mm Hg and a pH of 7.4. A midline sternal splitting thoracotomy was made and the heart suspended in a pericardial cradle exposing the distribution of the left anterior descending coronary artery. Aortic pressure, left ventricular pressure, and lead II of the electrocardiogram were continuously monitored.

The left anterior descending coronary artery was reversibly occluded just distal to the 1st or 2nd diagonal branch using a nontraumatic rubber ligature producing an area of ischemia approximately 25 to 30% of the total left ventricular mass. In 7 animals the ligature was applied for 15 minutes and then released with reperfusion of the ischemic zone carried out for an additional 120 minutes. A 2nd group of 8 animals had coronary occlusion for 30 minutes followed by reperfusion for 120 minutes. A 3rd group of 8 animals had coronary occlusion for 120 minutes followed by reperfusion for 120 minutes. The coronary vein was preserved in each case to allow venous washout during reperfusion.

Ventricular arrhythmia during occlusion was treated with minimal effective doses of lidocaine or, in the case of ventricular fibrillation, with electric countershock. At the end of reperfusion, 2.5 cc of 10% alphazurine 2-G blue dye was injected in a systemic vein to identify areas of the myocardium not well perfused. This dye stains perfused and presumably viable tissue a vivid blue but does not stain ischemic or nonperfused tissue[18] and has no effect on mitochondrial function or sarcoplasmic reticulum calcium transport. Immediately after injection of the dye, the heart was removed and taken to a cold room where samples were excised from uninvolved and reperfused areas of the left ventricle using surface anatomy and dye staining as guidelines. The posterior aspect of uninvolved left ventricle was used for sampling and was considered as a control for metabolic studies.

Echocardiographic methods: Left ventricular wall thickness was measured serially before and after occlusion by placing a 5.0 MHz nonfocused ultrasound transducer directly over the involved left ventricle. The transducer was coupled to an Echoline 20A ultrasonoscope (Smith Kline and French) with data being recorded on a strip chart recorder (Honeywell). To avoid pressure artifact and distortion of the heart wall, the transducer was held very lightly in contact with the epicardial surface over the center of the involved area of left ventricle, using the coronary artery surface anatomy as a landmark. The ischemic area was easily identified by the dark coloration and verified by S-T segment elevation on the epicardial electrode mapping over the involved area. This hand-held method resulted in reproducible echocardiographic data by assuring perpendicular orientation of the transducer with respect to the epicardial surface. Wall thickness was measured in millimeters at midsystole and end-diastole, with each final measurement being the mean of 5 consecutive cardiac cycles. The transducer itself caused a 3 mm layer visible as a dark stripe at the top of the echocardiograph. This thickness was subtracted from the total thickness for purposes of calculation.

Metabolic procedures: Tissue samples from control and reperfused left ventricles were homogenized with a Polytron PT-10 homogenizer at low speed in a medium containing 0.25 *M* sucrose and 20 m*M* Tris buffer (pH 7.5). Mitochondria were isolated by a method previously described.[19] After the final washing, mitochondria were suspended in a medium containing 0.1 m*M* Hepes potassium (N-2-hydroxyethylpiperazine-N′-2-ethanesulfonic acid) buffer (pH 7.4), with 250 m*M* sucrose. Mitochondria from ischemic, reperfused myocardium are very fragile.[20] The yield of mitochondrial protein measured by total protein content from ischemic, reperfused myocardium is much lower than that from nonischemic tissue. Mitochondrial protein was determined by the Biuret method.[21] Incubation mixtures contained 20 m*M* Tris buffer (pH 7.4), 100 m*M* sucrose, 100 m*M* potassium chloride, 5 m*M* inorganic phosphate, and 10 m*M* of either glutamate or malate plus pyruvate as substrate. Oxygen uptake was determined polarographically with a Clark electrode.[22] Adenosine diphosphate (ADP), 300 nmol, was added to the reaction mixture to initiate mitochondrial respiration. All reactions were carried out at 30°C. Uptake of calcium by mitochondria was monitored with the use of an oxygen electrode and a sensitive re-

cording pH electrode, as previously described.[23] Calcium uptake was also determined with $^{45}Ca^{2+}$ at a designated time after the addition of $^{45}CaCl_2$ by rapidly filtering the incubation mixture through a millipore filter.[24] The radioactivity of $^{45}Ca^{2+}$ of each sample was determined with a liquid scintillation spectrometer (Beckman). Sarcoplasmic reticulum vesicles were isolated from control and ischemic myocardium using the method described by Harigaya and Schwartz.[25] The kinetic features of calcium uptake by sarcoplasmic reticulum vesicle were determined with the use of murexide and dual wave-length spectrophotometry for measurement. The extent of calcium uptake by sarcoplasmic reticulum vesicles was studied by the use of radioactive $^{45}Ca^{2+}$ in the presence of oxalate.[24]

Tissue adenosine triphosphate (ATP) content was determined on duplicate tissue samples obtained by plunge biopsy using a renal biopsy needle (Travenol) just before sacrificing the animal. The needle was cooled in liquid nitrogen, plunged into the heart to obtain tissue, and immediately returned to a vial containing liquid nitrogen. Tissue for ATP determination was thus removed and frozen within 3 to 5 seconds. These samples were extracted in boiling water and ATP content was determined by firefly luciferase reaction.[26]

Samples from control and reperfused left ventricles were also taken for histologic section and examined by light microscopy for hemorrhage, with the degree of hemorrhage on each section being scored subjectively as none, slight, moderate, or severe. Water content of control and reperfused tissue samples was determined by weighing samples before and after 24 hours of dessication in a freeze-dryer (Virtis model 10-147 MRBA).

Tissue and mitochondrial samples for calcium content were extracted by a glacial acetic acid-trichloroacetic acid mixture,[27] and total calcium content was determined with an atomic absorption spectrophotometer with calcium carbonate as the standard.[28]

Data are presented as mean ± standard deviation and analyzed using Student's paired *t* test.

Results

Gross and microscopic findings: Within 1 to 2 minutes of coronary occlusion and ischemia the involved segment of left ventricle in all three groups of animals demonstrated cyanosis, flattened veins and arteries, and paradoxic systolic bulging, which persisted throughout occlusion. On reperfusion the coronary arteries and veins of the involved segment became distended and myocardial color was restored. The involved segment from 30 and 120 minute groups became firm to palpation compared with uninvolved areas of left ventricle on reperfusion. This effect was subjectively less evident in the 15 minute group and improved with time. When samples were taken from the left ventricle at the end of each experiment, reperfused areas of 30 and 120 minute groups had a firm texture compared with the near-normal tone of the 15 minute group and with the soft pliable uninvolved myocardium.

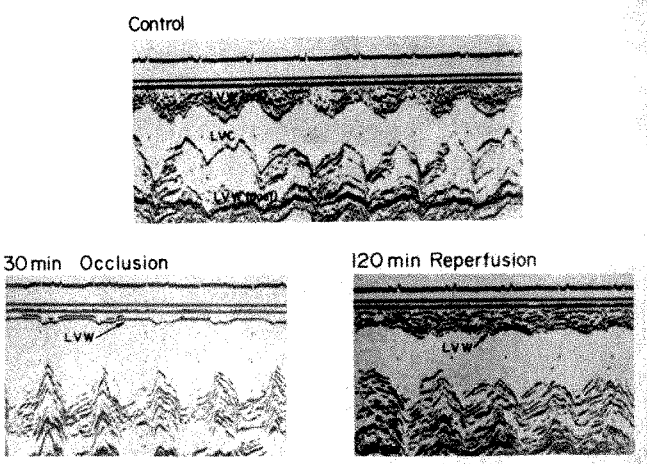

FIGURE 2. The panel arrangements are identical to those in Figure 1, but the occlusion time is 30 minutes. Note marked diastolic thickening of the anterior left ventricular wall (LVW) with minimal systolic thickening after reperfusion.

Review of microscopic sections showed no hemorrhage in areas of control left ventricle from the 15, 30, or 120 minute ischemia groups; no hemorrhage in reperfused areas of the 15 minute ischemic group; slight hemorrhage in reperfused areas of the 30 minute ischemic animals; and severe hemorrhage in sections of reperfused tissue from the 120 minute ischemia group.

Left ventricular wall thickness: Thinning of the ischemic myocardium occurred promptly and persisted

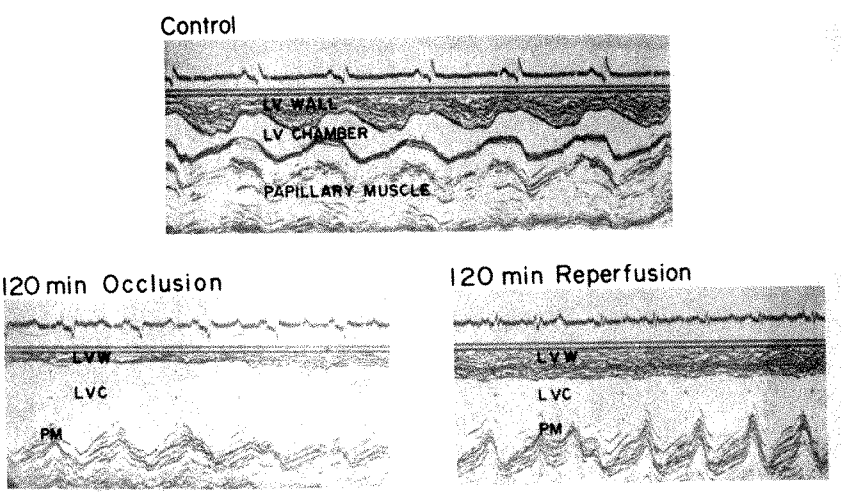

FIGURE 3. The panel arrangements are identical to those in Figure 1, but the occlusion time is 120 minutes. Note the marked thickening of the anterior left ventricular wall (LVW) with no wall motion. PM = papillary muscle.

throughout occlusion. This thinning was accompanied by systolic expansion of the ischemic area, which was also maintained until reperfusion. Representative echocardiographic changes in wall thickness at the center of the ischemic area for 1 animal in each of the 15, 30, and 120 minute groups are shown in Figures 1 to 3. During the control period in each illustration (top panel), the anterior myocardial thickening illustrates normal systolic wall motion. During occlusion of 15, 30, or 120 minutes (bottom left panel), there is loss of contraction and diastolic and systolic wall thinning. After reperfusion (bottom right panel) there is systolic thickening and diastolic thinning, comparing favorably with the control in the 15 minute ischemia group. After reperfusion in the 30 minute group, the anterior wall is thickened and there is minimal systolic thickening. In the 120 minute group prominent thickening of the anterior myocardial wall is seen without systolic or diastolic motion.

The variability of thickening of the ischemic left ventricle after reperfusion is illustrated for all animals in the 3 groups (Fig. 4 to 6). Control values are comparable for all groups. In the 15 minute ischemia group during reperfusion (Fig. 4), systolic anterior wall thickening improves gradually, ultimately approaching 75% of the control, and diastolic thinning is essentially normal. These findings contrast with the 30 (Fig. 5) and 120 minute ischemia (Fig. 6) groups in which effective systolic thickening and diastolic thinning are lost. The range of values is somewhat greater in the 30 minute group because of resumption of a measure of systolic thickening in 3 of 8 animals.

Metabolic data: Table I illustrates the results of oxidative phosphorylation for mitochondria prepared from control and reperfused tissue for the 15, 30, and 120 minute ischemia groups. Indexes of oxidative phosphorylation, including state 3 respiration (QO_2), ADP/O ratio, and respiratory control index (RCI), are shown. There was no significant difference for any of these variables for control tissue from the 15, 30, or 120 minute ischemia groups. In reperfused preparations, state 3 respiration, ADP/O ratio, and respiratory control index of mitochondria were slightly decreased in the 15 minute ischemia group. These variables were markedly decreased in the 30 and 120 minute ischemia groups compared with the 15 minute group ($p < 0.001$). These results suggest that mitochondria subjected to 15 minutes of ischemia and reperfusion were able to generate ATP with relatively normal efficiency. In contrast, oxidative phosphorylation was markedly impaired after 30 and 120 minutes of ischemia and reperfusion.

Figure 7 is a typical example of oxygen and pH electrode recording of Ca^{2+} uptake by mitochondria. The rate of Ca^{2+}-induced oxygen consumption and H^+ ejection by mitochondria is shown in each tracing. The rate of Ca^{2+} uptake was measured by the rate of H^+ ejection at the initial 10 seconds after Ca^{2+} was added.

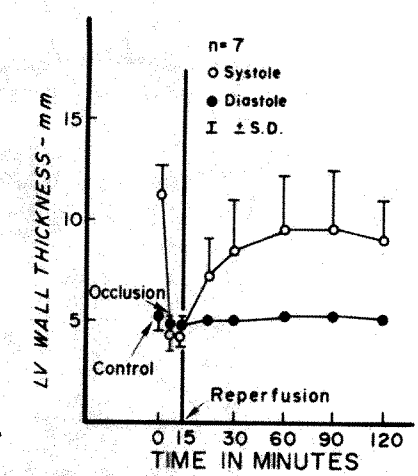

FIGURE 4. Systolic and diastolic left ventricular (LV) wall thickness (mm, mean ± standard deviation [SD]) for all 7 animals with coronary occlusion of 15 minutes. Results obtained during the control period, occlusion, and reperfusion are illustrated.

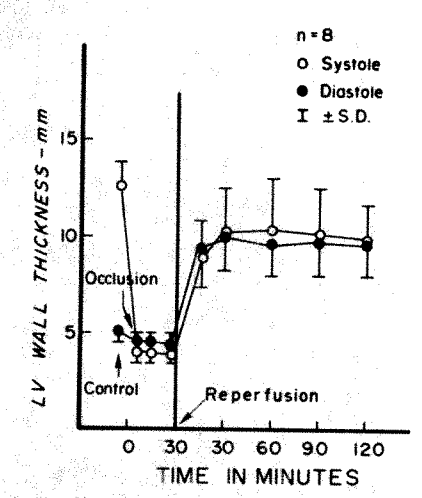

FIGURE 5. Systolic and diastolic left ventricular wall thickness (mm, mean ± SD) for all 8 animals with coronary occlusion of 30 minutes. Results obtained during the control period, occlusion, and reperfusion are illustrated.

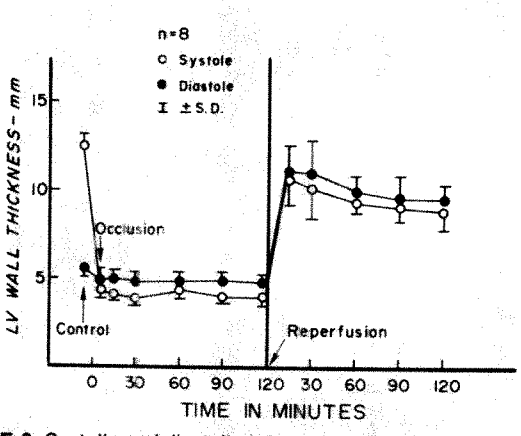

FIGURE 6. Systolic and diastolic left ventricular wall thickness (mm, mean ± SD) for all 8 animals with a coronary occlusion of 120 minutes is shown. Results obtained during the control period, occlusion, and reperfusion are illustrated.

TABLE I Mitochondrial Oxidative Phosphorylation After 15, 30, or 120 Minutes of Coronary Occlusion and 120 Minutes of Reperfusion

Group	QO_2 (ng atoms O/mg/min)	ATP/O	RCI
15 minute ischemia			
Control LV	287 ± 38	2.7 ± 0.3	9 ± 2
Reperfused LV	268 ± 36	2.4 ± 0.3	8 ± 2
30 minute ischemia			
Control LV	287 ± 50	2.6 ± 0.2	10 ± 3
Reperfused LV	133 ± 59*	1.7 ± 0.3*	4 ± 1*
p	<0.001	<0.001	<0.001
120 minute ischemia			
Control LV	288 ± 65	2.6 ± 0.2	9 ± 2
Reperfused LV	11 ± 4*	0.4 ± 0.1*	1.5 ± 0.5*
p	<0.001	<0.001	<0.001

* In addition to the p values shown between the control and reperfused left ventricle (LV) in each group, there was a significant difference ($p < 0.001$) in the reperfused LV of the 30 and 120 minute ischemia groups compared with the 15 minute reperfused LV.

ATP = adenosine triphosphate; QO_2 = oxygen consumption; O = oxygen; RCI = respiratory control index.

TABLE II Mitochondrial Ca^{2+} Content and Myocardial Ca^{2+} and ATP Content After 15, 30, or 120 Minutes of Ischemia and 120 Minutes of Reperfusion

Group	Mitochondrial Ca^{2+} (nmol/mg)	Tissue Ca^{2+} (μmol Weight)/g Wet	ATP (nmol/mg Protein)
15 minute ischemia			
Control LV	14 ± 4	1.2 ± 0.2	6.8 ± 3.6
Reperfused LV	16 ± 5	1.3 ± 0.2	4.8 ± 1.4
30 minute ischemia			
Control LV	13 ± 3	1.2 ± 0.3	6.6 ± 3.9
Reperfused LV	50 ± 11*	5.9 ± 1.9*	3.2 ± 1.8†
p	<0.001	<0.001	<0.01
120 minute ischemia			
Control LV	17 ± 5	1.2 ± 0.2	6.7 ± 3.0
Reperfused LV	43 ± 24*	5.0 ± 0.9*	1.2 ± 1.0*
p	<0.001	<0.001	<0.001

* In addition to p values shown between control and reperfused left ventricle (LV) in each group, there was a significant difference ($p < 0.001$) in the reperfused LV of 30 and 120 minute ischemia groups when compared with the 15 minute reperfused LV.

† Difference ($p < 0.01$) between reperfused LV in 30 minute group compared with 15 minute reperfused LV.

A slight decrease in Ca^{2+}-induced respiration and H^+ ejection was observed in the 15 minute ischemia group. This Ca^{2+}-induced respiration and H^+ ejection decreased from 126 ng atoms O/mg/min and 284 nmol H^+/mg/min in the control group to 62 and 144, respectively, in the 30 minute ischemia group. These respective values were further decreased to 8 ng atoms O/mg/min and 17 nmol H^+/mg/min in the 120 minute ischemia group. Furthermore, Ca^{2+} accumulation by mitochondria 1 minute after the addition of $^{45}Ca^{2+}$ was 167, 142, 79, and 10 nmol/mg of protein for the control group and 15, 30, and 120 minute ischemia groups, respectively.

Mitochondrial Ca^{2+} content and myocardial tissue levels of Ca^{2+} and ATP are shown in Table II. There was no difference between control myocardium and 15 minute ischemic myocardium for mitochondrial Ca^{2+} and tissue Ca^{2+} content. However, mitochondrial and myocardial Ca^{2+} levels increased significantly in the 30 and 120 minute ischemia groups. ATP content of tissue after 15 minutes of ischemia and 2 hours of reperfusion was only slightly decreased whereas a progressive decrease was observed in the 30 and 120 minute ischemia groups.

Table III shows that Ca^{2+} uptake by isolated sarcoplasmic reticulum vesicles decreased slightly in the

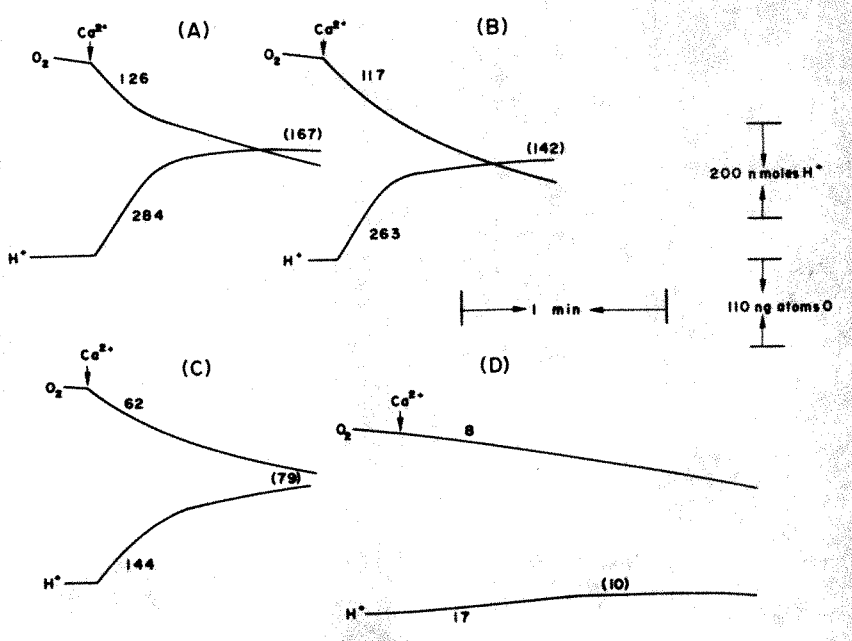

FIGURE 7. Oxygen and pH electrode tracings showing the rate of Ca^{2+}-induced respiration and H^+ ejection of mitochondria. The experimental system contains 1.0 m*M* Hepes buffer, pH 7.4, 100 m*M* KCl, 100 m*M* sucrose, 1 m*M* potassium phosphate monobasic, and mitochondria (2.0 to 2.2 mg protein). Ca^{2+} (400 nmol) was added to the incubation mixture to initiate the reaction in a final volume of 2.0 ml at 30°C as indicated. The number adjacent to each oxygen and pH electrode tracing represents the rate of oxygen consumption (ng atoms O/mg/min) and H^+ ejection (nmol H^+/mg/min) by mitochondria. Numbers included in parentheses represent $^{45}Ca^{2+}$ uptake by mitochondria (nmol Ca^{2+}/mg protein) 1 minute after $^{45}Ca^{2+}$ was added. **A,** mitochondria from control left ventricle; **B,** mitochondria from 15 minute ischemic and reperfused left ventricle; **C,** mitochondria from 30 minute ischemic and reperfused left ventricle; **D,** mitochondria from 120 minute ischemic and reperfused left ventricle.

TABLE III Calcium Uptake by Sarcoplasmic Reticulum Vesicles

Group	Rate of Ca^{2+} Uptake (nmol/mg/min)	
	Control LV	Reperfused LV
15 minute ischemia	249 ± 41	201 ± 24
30 minute ischemia	239 ± 26	113 ± 47*
120 minute ischemia	255 ± 28	27 ± 14*

* Significant difference from reperfused left ventricle (LV) in the 30 and 120 minute ischemia groups when compared with the 15 minute ischemia group, $p < 0.001$. Incubation system contained 20 m*M* Tris maleate buffer, pH 6.9, 100 m*M* KCl, 10 m*M* $MgSO_4$, 3 m*M* sodium oxalate, 0.3 m*M* murexide, Ca^{2+} (400 nmol), sarcoplasmic reticulum vesicles (0.4 mg), 4 μg oligomycin (to inhibit a possible contamination from any mitochondrial Ca^{2+} accumulation), and 3 m*M* ATP in a final volume of 3 ml at 23°C. The rate of Ca^{2+} uptake is determined from the dual-beam spectrophotometric trace as previously described.[25]

15 minute ischemia group when compared with those from the control left ventricle. The rate of Ca^{2+} uptake by sarcoplasmic reticulum vesicles was further decreased from 239 and 255 nmol/mg/min in control tissue to 113 and 27 in the 30 and 120 minute ischemia groups, respectively.

Water content of the control myocardium was 79.1 ± 0.7%. In the 30 minute ischemia group it was 83.3 ± 0.8 ($p < 0.01$) and in the 120 minute group it was 82.9 ± 0.8 ($p < 0.01$). Data for water content were unavailable for the 15 minute group.

Discussion

Reduced myocardial performance after transient coronary occlusion followed by reperfusion: Echocardiographic measurements of wall thickness show lack of systolic thickening and marked thinning during both systole and diastole promptly after acute coronary occlusion. This thinning persisted throughout the length of occlusion in all 3 groups of animals. Abrupt loss of contractile activity and wall thinning with ischemia has been reported by others.[10,29,30] The mechanism of these changes has been attributed to sudden loss of oxygen and loss of substrate delivery to the energy-producing sites, with cessation of ATP formation. Without energy production there is an inability to generate or maintain tension, an increase in compliance,[31] and passive thinning of the involved segment resulting from pressure developed in the left ventricle by the remaining normal myocardium. This effect is recognized grossly by systolic expansion of the ischemic zone. In our study reperfusion of the ischemic zone after 30 and 120 minutes of ischemia resulted in thickening of the left ventricular wall; however, this was not true for the 15 minute group. In the 30 minute ischemia group, there was not a significant return of ventricular performance as a whole, although 3 of 8 animals in this group did show evidence of slight systolic thickening.

Recently, myocardial perfusion was shown to be abnormal for prolonged periods after transient ischemia in the dog, and contractility abnormalities were previously documented to persist beyond the return of metabolic function toward normal.[32] Our data substantiate the latter observations, but the mechanisms of reduced myocardial perfusion and performance persisting after transient coronary occlusion followed by reperfusion remain unknown.

Mechanism of diastolic wall thickening with reperfusion: The mechanism of wall thickening in diastole with reperfusion has been studied by others. Gaasch and Bernard[10] described transient increases in left ventricular wall thickness on reperfusion after relatively short periods of ischemia. These changes were judged to be related to the acute increase in coronary flow (reactive hyperemia) that occurs on ligature release. As reactive hyperemia is a transient phenomenon, it would seem unlikely that the prolonged increase in left ventricular wall thickness observed in our present experiments resulted merely from an increase in blood volume of involved myocardium. Although some investigators[12,33] showed a significant increase in edema formation and myocardial cell swelling with reperfusion, the small increase in tissue water seen in our study would not seem to account for the marked increase in wall thickness. Although focal microscopic edema may have been present, it is unlikely that gross edema plays a significant role in reperfusion-induced wall thickening.

Intramyocardial hemorrhage with reperfusion after ischemia times of 1 hour or longer was described[34] and in our study was prevalent on microscopic sections from animals after 120 minutes of ischemia. However, absence of or slight hemorrhage in the 30 minute ischemia group and total absence in the 15 minute ischemia group indicate that this mechanism is not the one responsible for the thickened left ventricular wall. Recent studies[35,36] suggest that the extent of hemorrhage associated with reperfusion is the consequence of injury due to ischemia rather than to reperfusion.

The role of mitochondrial damage in reperfusion-induced wall thickening is important, as evidenced by marked decreases in mitochondrial function in the 30 and 120 minute ischemia groups. Mitochondria isolated from reperfused areas of 30 minutes or more of ischemia were unable to efficiently generate ATP. The abnormalities of mitochondrial configurations and structures in irreversibly ischemic or ischemic-reperfused myocardium were previously reported.[20,37,38] Some electron-dense granules were observed in the swollen mitochondria in the ischemic myocardium on reperfusion. These granules were suggested to be either lipid components of the cell or some type of calcium phosphate complexes.[39,40] It is difficult to correlate closely the extent of morphologic integrity with biochemical alterations in these mitochondrial preparations. Electron-dense granules and swollen mitochondria have been observed in both sliced tissue sections and isolated preparations from irreversible ischemic myocardium.[20,37,38,40] It is generally believed that a certain degree of damage has already taken place in vivo during the ischemic insult before isolation procedures begin. Some investigators suspect that mechanical disruption

associated with isolation may also induce some degree of damage to mitochondrial structure and function, particularly to those from ischemic-reperfused myocardium. However, it is difficult to assess how much functional impairment is due to ischemic insult versus mechanical disruption. Nevertheless, this study shows a positive correlation between the abnormality of ventricular wall thickening and the alteration of mitochondrial function. Adverse effects on mitochondrial function were also previously demonstrated by Wood et al.[32] in the dog model. After short occlusion times of 5 and 10 minutes with reperfusion, mitochondrial function returned toward normal. However, with longer ischemic periods, mitochondrial function was depressed. Thus, the alteration in the biochemical function of mitochondria which results in impaired energy production may be one factor among others, such as capillary damage and cell swelling,[41–44] contributing to the development and persistence of regional wall thickening.

Calcium content of reperfused ischemia myocardium: A striking abnormality is the 5-fold increase in calcium content of tissue of the reperfused left ventricle from both 30 and 120 minute ischemia groups and the increased mitochondrial calcium. This increase was previously described.[43,44] Furthermore, calcium ion (Ca^{2+}) accumulation by mitochondria and sarcoplasmic reticulum vesicles was markedly deranged in both groups. These high levels of calcium ion in ischemic myocardium may have resulted from the inability to pump calcium ion out of the cell because of a defect in Ca^{2+}-dependent ATPase of the sarcolemma membrane as well as from the limited capacities of sarcoplasmic reticulum vesicles and mitochondria to remove cellular calcium ion. This, in turn, inhibits ATP production by mitochondria.[45] These high levels of calcium ion in tissue and low ATP produced by mitochondria may result in delay or failure of myocardial relaxation, a thickened left ventricular wall, and ischemic contracture with little or no return of function. The sequence of events described in our experiments is similar to that described by Cooley et al.[46] in the "stone heart syndrome" which occasionally developed in patients placed on cardiopulmonary bypass with normothermic ischemic arrest and may account for the "paradox of necrosis" in areas of revascularization after bypass surgery as described by Bulkley and Hutchins.[7] A recent study[47] describes failure of myocardial relaxation or ischemic contracture in rabbit hearts made ischemic and then reperfused. Accumulation of calcium in mitochondrial fractions isolated from the reperfused left ventricle paralleled the severity of contracture and lack of diastolic relaxation. In animals in that study treated with a calcium antagonist, nifedipine, contractures did not develop with reperfusion. Recently a study[48] using verapamil showed a favorable effect with better preservation of ATP generation and a more normal content of tissue and mitochondrial calcium ion.

Application to human experimental data: The findings of this study may relate to left ventricular performance and biochemical alterations of myocardium in man after reperfusion with thrombolytic agents in thrombotic acute myocardial infarction, after prolonged severe coronary spasm resulting in severe ischemia or infarction,[49,50] or in regionally ischemic areas of the myocardium after bypass surgery in some patients.[7] The extent of damage to the myocardium in these instances may ultimately be related to occlusion or reperfusion times and the presence or absence of coronary collaterals. The problem of nonuniformity of cellular damage and the potential for salvage of jeopardized cells has recently been critically discussed, particularly as it relates to the border zone of an infarction.[51] The complex issues of pathogenesis of myocardial infarction—thrombosis, spasm, and altered platelet activity as well as the dynamics of atherosclerosis—call for caution in extrapolation of experimental data to man; the need for careful studies in these areas was emphasized by Muller et al.[52] The arbitrary time period of 2 hours of reperfusion in our experimental protocol is a limiting factor in clinical application. Nevertheless, it is apparent that time after the onset of severe ischemia is critical if reperfusion is to reverse severe tissue damage and death.

The choice of the animal model deserves comment. There is no ideal model to simulate the usual circumstances of noteworthy coronary atherosclerosis that exist before acute ischemia.[53] The dog is frequently used because of the presence of preexisting coronary collateral vessels thought to resemble the situation in man. However, in acute infarction in man, collateral vessels, as determined by angiography, may be absent.[54] The pig is essentially free of coronary collateral vessels[17] and may serve as an acceptable model of this nature. Because of the interaction of coronary collateral circulation of the animal model chosen and varying ischemia and reperfusion time protocol, our data expand the information available in this vital area and serve as a comparison with animal models with different coronary perfusion patterns.

In conclusion, this study shows that ischemia for 30 or 120 minutes results in damaged myocardial cell membranes, allowing accumulation of calcium ion in tissue and mitochondria on reperfusion of the ischemic zone. This calcium ion accumulation then interferes with mitochondrial ATP production and apparently inhibits myocardial relaxation probably related in part to high calcium ion and low ATP levels. Marked diastolic thickening and lack of systolic thickening in the reperfused zone are observed. Relatively normal systolic thickening and diastolic thinning, mitochondrial function, sarcoplasmic reticulum calcium ion uptake, myocardial calcium ion, and ATP content after 15 minutes of ischemia followed by reperfusion were observed. These findings suggest that an irreversible cell membrane defect occurs between 15 and 30 minutes of ischemia if followed by reperfusion, and that this defect allows calcium accumulation resulting in a reduction of myocardial performance including effective diastolic relaxation and systolic contraction.

Acknowledgment

We are grateful for the expert technical assistance of Wesley Crook, Jackie Gammill, Charles King, William Lynch, and Joyce Massengill and for manuscript preparation by Diane Butler. We also thank Ralph Haskins for calcium determinations.

Effect of Intraaortic Balloon Counterpulsation on Regional Myocardial Blood Flow and Oxygen Consumption In the Presence of Coronary Artery Stenosis: Observations in an Awake Animal Model

HENRY GEWIRTZ, MD, WILLIAM OHLEY, PhD, DAVID O. WILLIAMS, MD, YING SUN, MSEE, and ALBERT S. MOST, MD

The mechanism by which intraaortic balloon pumping ameliorates myocardial ischemia in patients with unstable angina pectoris is uncertain. Accordingly, the following study was performed to determine the effect of intraaortic balloon pumping on regional myocardial blood flow and myocardial oxygen consumption (MVO_2) distal to severe coronary artery stenosis. Nine closed chest conscious pigs were instrumented with a 7.5 mm long plastic stenosis which reduced vessel diameter by 82%. Measurements of hemodynamics, regional myocardial blood flow (microsphere technique) and MVO_2 were made (1) before intraaortic balloon pumping, (2) at the end of 15 to 20 minutes of intraaortic balloon pumping, and (3) 20 minutes after its discontinuation.

Control endocardial blood flow ($ml \cdot min^{-1} \cdot g^{-1}$) distal to the stenosis (1.04 ± 0.20, mean ± 1 standard deviation [SD]) was less than endocardial flow in myocardium perfused by the unobstructed circumflex coronary artery (1.67 ± 0.77, $p < 0.01$). Likewise, control distal zone epicardial flow (1.16 ± 0.36) was reduced in comparison with control circumflex zone epicardial flow (1.48 ± 0.60, $p < 0.01$).

In response to intraaortic balloon pumping rate-pressure product declined versus control (10,300 ± 2,090 [SD] mm $Hg \cdot min^{-1}$ to 9,110 ± 2,010, $p < 0.005$), whereas aortic mean diastolic pressure (mm Hg) increased versus control (109.0 ± 9.9 to 121.0 ± 13.8, $p < 0.01$). Distal coronary mean diastolic pressure did not change in response to intraaortic balloon pumping (61.9 ± 13.0 to 68.7 ± 16.5, p = NS). Likewise, endocardial blood flow ($ml \cdot min^{-1} \cdot g^{-1}$) distal to the stenosis did not change during intraaortic balloon pumping (1.00 ± 0.24) versus control (1.04 ± 0.20). In contrast, during intraaortic balloon pumping epicardial blood flow distal to the stenosis declined versus control (1.16 ± 0.36 to 1.01 ± 0.27, $p < 0.05$). Regional MVO_2 ($ml \cdot min^{-1} \cdot 100\ g^{-1}$) distal to the stenosis also decreased versus control in response to intraaortic balloon pumping (12.90 ± 3.55 to 10.30 ± 2.52, $p < 0.05$). Furthermore, regional MVO_2 correlated well ($r = 0.74$, $p < 0.002$) with rate-pressure product.

Thus, intraaortic balloon pumping reduces myocardial oxygen demand but does not improve blood flow distal to a severe coronary stenosis; (2) blood flow distal to a severe stenosis may fail to increase with intraaortic balloon pumping because (A) distal coronary mean diastolic pressure may not increase, and (B) blood vessels distal to the stenosis tend to autoregulate in response to a decline in myocardial oxygen demand; and (3) intraaortic balloon pumping ameliorates myocardial ischemia in patients with unstable angina pectoris primarily by reducing oxygen demand rather than by increasing oxygen supply.

The use of intraaortic balloon pumping to produce arterial counterpulsation has been shown effective in relieving pain and controlling myocardial ischemia in patients with unstable angina pectoris.[1–4] Many patients generally have 1 or more severely stenosed but patent coronary arteries. The mechanism(s) by which arterial counterpulsation ameliorates myocardial ischemia in these patients has not been clearly defined. Because arterial counterpulsation reduces ventricular afterload and increases diastolic pressure in the aorta,[5–9] it may be effective either by reducing myocardial oxygen demand or by increasing oxygen supply, or both. However, firm proof that arterial counterpulsation actually increases blood flow distal to a severe coronary artery stenosis is not available. Gill et al.[10] measured an increase in myocardial blood flow distal to severe stenosis

of a circumflex coronary artery in an open chest canine preparation. However, in their study heart rate was not controlled or commented on. Thus, an increase in heart rate could have occurred during counterpulsation and may have been responsible for the increase in the observed flow. Furthermore, although many investigators have examined the effects of intraaortic balloon pumping on regional blood flow distal to a ligated coronary artery, the results have been inconsistent; some investigators[11–13] reported an increase in collateral flow in response to balloon pumping alone whereas others[14–17] observed no change in flow. In light of these considerations we performed studies in a closed chest porcine model instrumented with a severe intraluminal coronary artery stenosis[18] in order to test the hypothesis that arterial counterpulsation is effective in relieving myocardial ischemia in the setting of a stenosed but patent coronary artery primarily by virtue of its ability to reduce myocardial oxygen demand rather than by increasing oxygen supply.

Methods

Animal preparation: Nine farm-bred pigs (mean weight 41.9 kg, range 35.6 to 49.6) were anesthetized with halothane (0.5 to 1.5%) and nitrous oxide, intubated, and ventilated with a volume-cycled respirator. After the animal was heparinized (225 IU·kg^{-1}) a 6Fr end hole catheter was inserted into the left brachial artery and advanced into the subclavian artery. This line was used to monitor pressure, to obtain samples of blood for pH, PO_2 and PCO_2, and for withdrawal of blood for determination of regional myocardial blood flow (microsphere technique). A 40 ml intraaortic balloon (PERCOR-40™, Datascope, Paramus, New Jersey) was inserted in the left femoral artery. The distal end of the balloon was advanced under fluoroscopic control to the arch of the aorta and positioned just below the subclavian artery. The right femoral artery was used to insert an 8Fr angiographic catheter which was passed retrograde under fluoroscopic guidance into the left atrium through the left ventricle. This catheter was used to administer radioactive microspheres. A 7Fr "head-hunter" catheter (USCI, Billerica, Massachusetts) inserted into the right internal jugular vein was advanced under fluoroscopic control into the coronary sinus and then to the proximal portion of the anterior interventricular vein. This catheter was used to sample coronary venous blood draining myocardium in the distribution of the left anterior descending coronary artery.

The animal's heart was paced at a constant rate throughout the study by means of a 7Fr bipolar catheter positioned in the proximal portion of the coronary sinus. An 8Fr Amplatz catheter was inserted into the right carotid artery and advanced under fluoroscopic control to the left anterior descending coronary artery. The artery was visualized by hand injection of 3 to 5 ml Renografin-76™ after which an 0.018 Teflon®-coated guidewire with a 3 cm floppy distal end was inserted into the vessel. The Amplatz catheter was removed and a plastic stenosis (7.5 mm long, outside diameter 3.5 mm, inside diameter 0.625 mm) loaded onto the wire and advanced down it into the proximal 3rd of the coronary artery. The wire was quickly removed, leaving the stenosis in place. The stenosis contained a 2nd lumen into which the distal end of a 1.0 mm diameter, 70 cm long plastic catheter had been attached before placement of the stenosis. The distal end of the catheter was open to the distal end of the stenosis and was used to record distal coronary pressure in the left anterior descending artery. Finally, an 8Fr micromanometer tip catheter (Millar Instruments, Houston, Texas) was inserted into the left ventricle through the right carotid artery. This completed the preparation of the animal. After instrumentation had been accomplished, all cutdown sites were closed and the animal permitted to awaken from anesthesia. Small doses (20 to 40 mg) of sodium thiamylol were then given intravenously throughout the study to insure that the animal was comfortable and rested quietly. Although sedated, the animal breathed spontaneously, was awake, and had brisk corneal reflexes.

Experimental protocol: On the day before the study each animal was given aspirin (150 mg orally) to prevent platelet aggregation within the lumen of the stenosis.[19] After instrumentation had been completed, propranolol (1 to 2 mg·kg^{-1}) was given intravenously. After 15 to 20 minutes after a stable baseline heart rate had been established, atrial pacing was begun at a rate of 10 to 15 beats/min above baseline. Pacing was continued at this rate for the remainder of the study. Control measurement of hemodynamics (see later), regional myocardial blood flow, and regional oxygen metabolism (see later) were then obtained after 15 minutes of atrial pacing at a constant rate. Next, the intraaortic balloon pump was turned on and counterpulsation maintained for 15 to 20 minutes. The balloon pump was phased with a Datascope control unit (model 3510) so as to produce maximal attainable systolic unloading of the left ventricle along with maximal attainable augmentation of diastolic pressure in the aorta. At the end of 15 to 20 minutes of balloon counterpulsation, hemodynamic, regional myocardial blood flow, and metabolic measurements were repeated. The balloon pump was then turned off and 20 minutes allowed to elapse after which all measurements were repeated. Thereafter, the animal was killed and the heart removed and sectioned for determination of microsphere activity (see later).

Acquisition and analysis of hemodynamic data: All pressures except those from the left ventricle were obtained with fluid-filled catheters and Hewlett-Packard transducers (model 1280). Left ventricular pressures were recorded from a solid state micromanometer tip catheter which was balanced electronically and calibrated with reference to pressure obtained from the fluid-filled catheter in the left atrium. The frequency response of the narrow lumen catheter used to record pressure distal to the stenosis exhibited an acceptable frequency response (3 db roll-off at 5.5 Hz) when tested in vitro. Because the heart rates encountered in this study were less than 1.5 Hz in all but 1 animal in which the rate was 1.83 Hz, it can be shown that 90 to 95% of all phasic information in the arterial wave form could be recovered with this system.[20]

All pressure signals were digitized simultaneously on-line with the aid of a PDP 11/40 computer system and 12 bit analog-to-digital converter. Because pressures were sampled at 200 Hz over a dynamic range of 0 to 300 mm Hg, we were able to resolve pressure changes to ±0.07 mm Hg. Ten second data acquisitions were obtained for each experimental condition. The animal's electrocardiogram (lead II) also was digitized on-line along with the pressure signals in order to detect the R wave that was used for timing purposes. The signals were then formatted with respect to the R wave into an average cardiac cycle using the forward and reverse averaging technique of Bacharach et al.[21] The computer also was used to determine maximal, minimal, mean systolic, mean diastolic, and overall mean pressure in the left ventricle, aorta, and distal coronary artery for each phase of the study. Left ventricular end-diastolic pressure, the left ventricular tension-time index (area under the systolic portion of the left ventricular pressure trace multiplied by heart rate [per second]), and maximal positive left ventricular dP/dt (first derivative of left ventricular pressure) also were determined by the

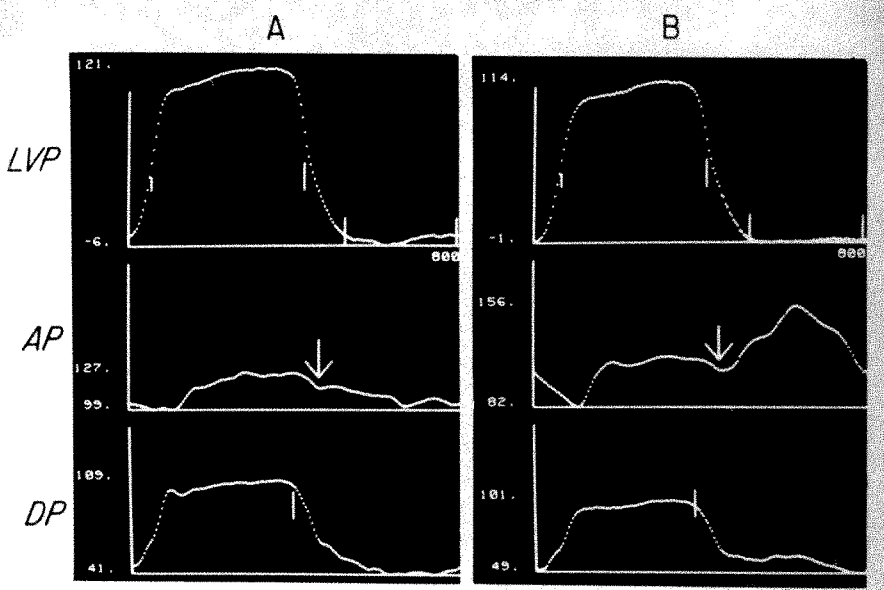

FIGURE 1. Left ventricular (LVP), aortic (AP), and distal coronary artery (DP) pressure wave forms for an average cardiac cycle obtained under control conditions (**panel A**) and during arterial counterpulsation (**panel B**). The **vertical bars** on the left ventricular pressure trace indicate computer-identified points for maximal positive and negative left ventricular dP/dt. Similarly, the **arrow** on the aortic pressure trace indicates the computer-identified position of the dicrotic notch. Mean diastolic pressure (area under the curve divided by time) was determined between the dicrotic notch and the point of minimal aortic pressure. The **vertical bar** on the distal coronary pressure trace marks the computer identified onset of diastole. This point was defined as the point that preceded the point of maximal negative left ventricular dP/dt by 20 ms. End-diastole was defined as the point on the distal pressure trace that coincided with the R wave of the electrocardiogram. Note that counterpulsation produced a substantial increase in aortic diastolic pressure along with a decrease in left ventricular mean systolic pressure. Distal coronary mean diastolic pressure also was augmented by counterpulsation in this animal, although the pressure wave form was not altered substantially.

computer. Two examples of typical records obtained from 1 of the animals used in the study are shown in Figure 1. All hemodynamic measurements for each phase of the study were made from the computer-generated average cardiac cycle.

Acquisition of regional myocardial oxygen consumption data: Paired samples (2 to 3 ml) of arterial and anterior interventricular vein blood were obtained for determination of oxygen content (Lex-O_2-CON Instrument, Lexington Instruments, Waltham, Massachusetts) during each phase of the study. Samples were obtained immediately after each determination of regional myocardial blood flow. Blood samples were collected in heparinized glass syringes and immediately placed on ice for subsequent analysis at the end of the study. Oxygen content (vol/100 ml) was determined in duplicate for each sample and values were accepted only if both readings agreed to within ± 0.2 vol/100 ml. Regional myocardial oxygen consumption ($ml \cdot min^{-1} \cdot 100\ g^{-1}$) was calculated as the product of transmural regional myocardial blood flow distal to the stenosis and the arterial-anterior interventricular vein oxygen difference.

After the animal had been killed the position of the distal end of the anterior interventricular vein catheter was carefully noted with respect to (1) its location in relation to the proximal end of the artificial stenosis, and (2) the presence of any large venous tributaries arising from myocardium not perfused by the stenosed portion of the left anterior descending artery. We observed no major venous tributaries arising from normally perfused myocardium emptying into the anterior interventricular vein distal to the distal end of the indwelling catheter in any of the animals in which regional myocardial oxygen consumption data are reported (n = 7). The distal end of the anterior interventricular vein catheter came to rest an average of 2.2 cm (range 0.8 to 3.5) proximal to the level of the proximal end of the artificial stenosis.

Determination of regional myocardial blood flow: Regional myocardial blood flow was determined by the microsphere technique.[22] For each experimental condition approximately 4×10^6 radiolabeled microspheres (15 μm diameter, 85 to 105 μCi total radioactivity) were injected through the left atrial catheter. A precisely timed, 2 minute reference collection of arterial blood was begun 15 to 30 seconds before injection of the radiolabeled microspheres. Blood was withdrawn at a constant rate (10 ml/min) from the subclavian artery catheter into a 50 ml preweighed glass syringe by means of a Harvard pump. It also should be noted that (1) a different radioisotope was chosen at random for each flow determination, and (2) the microspheres were suspended in 10% dextran with 0.01% Tween-80™ and sonically dispersed for 15 minutes before each injection. Finally, to precisely label myocardium distal to the stenosis, approximately 300,000 radiolabeled microspheres (15 μm diameter, total activity approximately 4.0 μCi) were injected into the distal coronary pressure catheter at the end of the study. The animal was killed by giving a large intravenous dose of sodium thiamylol (200 to 300 mg) and 3 to 5 minutes later a lethal dose of potassium chloride through the left atrial catheter.

After the animal was killed the heart was removed and sectioned for determination of microsphere activity. The free wall of the left ventricle was removed from the heart after which epicardial blood vessels and fat were carefully trimmed away. Next, the ventricle was cut into cubes weighing 2 to 3 g and the location of each carefully noted on a diagram of the free wall of the ventricle. Each cube was divided into endocardial and epicardial halves and placed in a preweighed plastic vial. The vials were reweighed and then counted in a gamma well counter (Packard Instruments, Downer Grove, Illinois). A computer was used to correct for spillover of counts from 1 isotope into the window of another and to calculate regional myocardial blood flow ($ml \cdot min^{-1} \cdot g^{-1}$) in each tissue sample. For purposes of analysis the free wall was divided into 2 zones: 1 at the base of the heart perfused by the circumflex coronary artery (circumflex zone) and the other perfused by the left anterior descending artery distal to the stenosis (distal zone). The latter area was readily identified because it contained a high concentration of marker microspheres ($7{,}000 \cdot g^{-1}$ or greater), whereas the circumflex zone contained none.

Additional animals (n = 5): A total of 5 additional animals were studied to confirm that the artificial stenosis caused regional myocardial ischemia under basal conditions (n = 2) and to facilitate interpretation of changes in regional myo-

TABLE I Hemodynamic Results (Mean ± 1 SD) of Intraaprtic Balloon Pumping (IABP) in 9 Pigs With a Severe Coronary Artery Stenosis

	Control I	IABP	Control II

cardial blood flow and oxygen consumption that occurred in response to balloon pumping (n = 3). Ultrasonic length sensors (Norland Corp., Fort Atkinson, Wisconsin) were inserted under sterile conditions near the endocardial surface of the left ventricle in each pig. One pair of sensors was placed near the base of the heart in an area perfused by the circumflex coronary artery, whereas the other pair was placed in the anterior free wall of the left ventricle in a region perfused by the distal ramifications of the left anterior descending coronary artery. A small polyethylene catheter (outside diameter 1.2 mm) was inserted into the left atrium and secured with a purse-string suture at the time of surgery. Both the catheter and wires from the piezoelectric crystals were tunneled through the chest wall and secured under the animal's skin behind the neck. Thereafter, the animal's chest was closed and air evacuated. Seven to 10 days later when recovered from surgery, the animal was returned to the laboratory for study.

In 2 animals anesthetized with halothane and nitrous oxide a 7Fr bipolar pacing catheter was placed in the coronary sinus and pacing was begun at a rate 10 to 15 min^{-1} above the animal's sinus rate. Once a steady state had been achieved for 10 to 15 minutes, radioactive microspheres were injected into the left atrial catheter to measure regional myocardial blood flow. Hemodynamics (heart rate, arterial pressure) and regional systolic function (ultrasonic length sensors) were recorded at the same time. Thereafter, the artificial stenosis was inserted into the animal's left anterior descending coronary artery and repeat measurements of all experimental variables obtained were 10 and 30 minutes later. As described previously, myocardium distal to the stenosis was objectively demarcated by infusion of a separate marker set of microspheres directly into the pressure catheter attached to the stenosis. The animal was then killed and the heart removed to determine microsphere activity and to confirm the location of the length sensors.

The other 3 animals were used to document the effect of balloon counterpulsation on regional myocardial function. These animals were prepared and instrumented in exactly the same fashion as described in Section 1 on animal preparation. After instrumentation was completed the animals were permitted to awaken from anesthesia. All animals were studied after beta blockade with propranolol and with heart rate controlled by means of atrial pacing at 10 to 15 min^{-1} above the animal's intrinsic rate. Once a steady state had been achieved, control measurements of regional myocardial blood flow, oxygen metabolism, systolic function, and hemodynamics were obtained. Next, the intraaortic balloon pump was turned on and phased so as to produce maximal systolic unloading along with maximal attainable augmentation of aortic diastolic pressure. At the end of 15 to 20 minutes of counterpulsation repeat measurements of all experimental variables were made. Thereafter, marker microspheres were given through the perfusion catheter and the animal was killed. The heart was removed and sectioned for determination of microsphere activity and to confirm the location of the length sensors.

Statistical methods: The significance of group mean changes (versus control) for hemodynamic, regional myocardial blood flow, and oxygen metabolism variables in response to arterial counterpulsation were assessed by means of a blocked 1-way analysis of variance and Dunnett's test.[23] Results were considered statistically significant when $p < 0.05$. All values are expressed as mean ±1 SD. Correlations between variables were assessed by means of a simple linear regression analysis.

Results

Group I (9 Animals Studied Before, During, and After Intraaortic Balloon Pumping)

Hemodynamics (Table I): As required by the study design, heart rate did not change significantly versus control in response to intraaortic balloon pumping. In contrast, peak left ventricular systolic pressure, rate pressure product (heart rate × peak left ventricular pressure), and tension time index all declined significantly ($p < 0.005$) versus control during arterial counterpulsation. As expected, intraaortic balloon pumping also produced a significant ($p < 0.01$) increase (versus control) in aortic mean diastolic pressure. Despite the fact that aortic mean diastolic pressure increased with arterial counterpulsation there was no significant change in distal coronary mean diastolic pressure for the group as a whole although 5 of 9 animals did exhibit an increase (18.1 ± 3.3% above control levels). However, distal coronary mean diastolic pressure failed to increase in 4 of the animals primarily because augmentation of early diastolic pressure by balloon inflation was offset by considerable lowering of late diastolic pressure when the balloon was deflated. Accordingly, the *mean* value of diastolic pressure distal to the stenosis failed to change versus control in these animals. Both distal coronary mean pressure and aortic mean pressure showed no significant change in response to balloon pumping. Left ventricular end-diastolic pressure did not change significantly during the study. Maximal positive

left ventricular dP/dt declined significantly in response to arterial counterpulsation. After discontinuation of balloon pumping all hemodynamic variables returned to control levels with the exception of the tension time index which remained modestly but significantly depressed versus its initial control value.

Regional myocardial blood flow (Table II; Fig. 2): Under control conditions, regional myocardial blood flow was reduced significantly in both endocardium and epicardium of the distal zone in comparison with respective flows in the circumflex zone. The ratio between distal and circumflex zone flows (endocardium and epicardium) did not change significantly during the study. In response to intraaortic balloon pumping both endocardial and epicardial blood flow in both distal and circumflex zones tended to decline compared with control. However, only the decrease in distal zone epicardial flow attained statistical significance. The decline in distal zone epicardial flow also was responsible for the statistically significant increase in the distal zone endocardial/epicardial blood flow ratio observed during arterial counterpulsation. In response to balloon pumping, the relative change versus control in blood flow in both distal zone endocardium (decline to 95.9 ± 8.6 % of control blood flow) and epicardium (89.8 ± 18.5 %) did not differ significantly from that of respective changes in blood flow in circumflex zone endocardium (90.0 ± 18.1 %) and epicardium (89.5 ± 19.0 %). A significant increase (versus levels during balloon pumping) in epicardial flow in both distal and circumflex zones was observed after discontinuation of arterial counterpulsation. Endocardial blood flow in both zones also tended to increase (versus levels during balloon pumping) after discontinuation of arterial counterpulsation although the changes failed to attain statistical significance.

TABLE II Regional Myocardial Blood Flow Response (ml·mn^{-1}·g^{-1}, Mean ± 1 SD) to Intraaortic Balloon Pumping (IABP) in 9 Pigs With a Severe Coronary Artery Stenosis

	Control I	IABP	Control II

Regional (distal zone) myocardial oxygen metabolism (Table III; Fig. 3): Two animals were omitted from analysis because it was not possible to properly position the anterior interventricular vein catheter. Intraaortic balloon pumping resulted in significant decreases (versus control) in the arterial-anterior in-

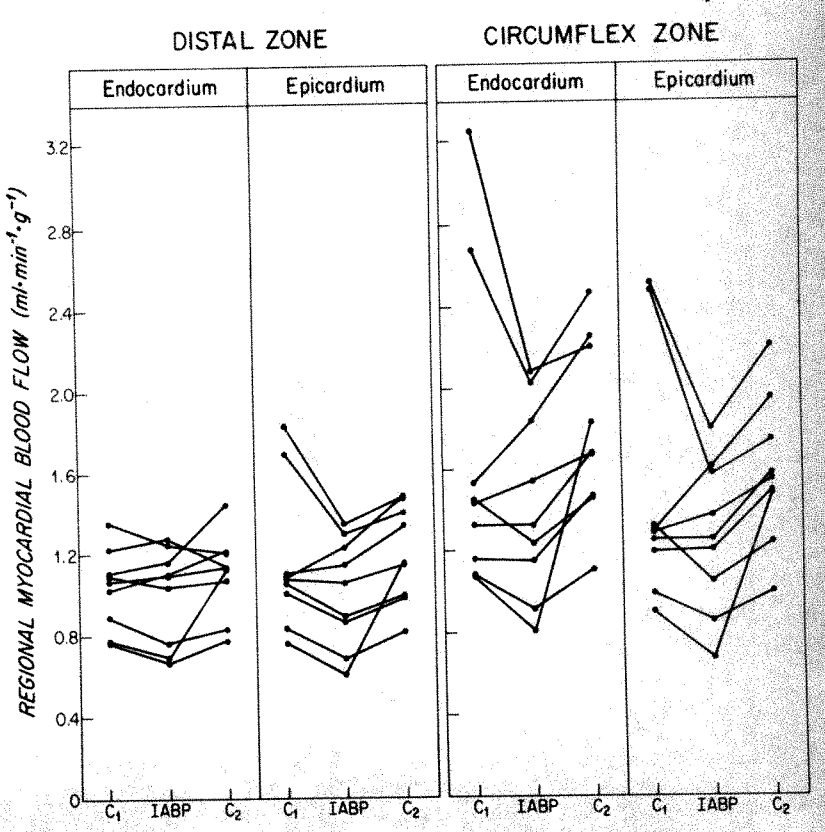

FIGURE 2. Individual responses to intraaortic balloon pumping (IABP) of distal and circumflex zone endocardial and epicardial blood flow (microsphere technique) for each of the 9 animals. Note that in response to IABP distal zone endocardial and epicardial blood flow either failed to increase substantially or else declined in all animals. The response of the circumflex zone was similar for both endocardium and epicardium. Discontinuation of balloon pumping was associated with an increase (versus levels during IABP) in blood flow in both endocardium and epicardium in both zones in all but 2 animals in which distal zone endocardial flow declined modestly after counterpulsation was stopped. C_1 and C_2 = control 1 and control 2 periods, respectively.

TABLE III Regional (Distal Zone) Myocardial Oxygen Metabolism: Results (Mean ± 1 SD) of Intraaortic Balloon Pumping (IABP) in 7 Pigs With a Severe Coronary Artery Stenosis

	Control I	IABP	Control II
Arterial oxygen content (vol/100 ml)	13.22 ± 1.08	12.41 ± 1.10*	12.08 ± 1.05*
AIV oxygen content (vol/100 ml)	1.46 ± 0.43	1.71 ± 0.66†	1.46 ± 0.64
Arterial-AIV oxygen difference (vol/100 ml)	11.76 ± 1.15	10.70 ± 1.22*	10.62 ± 0.93*
Regional myocardial oxygen extraction (%)	88.8 ± 3.7	86.2 ± 5.3†	88.0 ± 5.0
Regional myocardial oxygen consumption (ml·min^{-1}·100 g)	12.95 ± 3.55	10.26 ± 2.52†	11.72 ± 1.84

* $p < 0.01$ versus control I. † $p < 0.05$ versus control I.

terventricular vein oxygen difference, myocardial oxygen extraction, and oxygen consumption in the distal zone. After discontinuation of arterial counterpulsation, regional myocardial oxygen extraction and consumption both returned to values that did not differ significantly from those of control I. Finally, it should be noted that a strong linear correlation was observed between the rate-pressure product and distal zone regional myocardial oxygen consumption ($r = 0.74$, $p < 0.002$; pooled data consisting of 2 observations, control and intraaortic balloon pumping, in each of 7 animals).

Group II (Additional Animals) (n = 5)

Effects of insertion of the artificial stenosis on regional myocardial blood flow and function (n = 2 animals) (Table IV): In both animals changes in mean arterial pressure and heart rate were small (versus prestenosis control) after placement of the stenosis. In both animals prestenosis endocardial flows expressed as the ratio distal/circumflex flow declined 10 minutes after placement of the stenosis and remained at similar levels 30 minutes after placement. Also, the absolute value of endocardial flow in the distal zone declined (versus prestenosis control) in both animals after insertion of the stenosis. In the epicardial region the control flow ratio declined in both animals at 10 minutes after placement of the stenosis as did the absolute values of distal zone epicardial flows. Thirty minutes after placement, the distal/circumflex epicardial flow ratio remained depressed in 1 animal but returned to control levels in the other. Regional systolic function measured by mean velocity of circumferential fiber shortening (fractional shortening/ejection time) was depressed (versus control) in the distal zone at 10 and 30 minutes after placement of the stenosis in both animals. Thus, in both animals the stenosis caused a reduction in regional endocardial blood flow as well as evidence of impaired systolic function. Although epicardial blood flow declined only slightly after placement of the stenosis in the distal zone of these 2 animals, in the primary series (n = 9) the distal/circumflex epicardial flow ratio (0.81 ± 0.06) was less than that of the left anterior descending/circumflex epicardial flow ratio of 63 normal

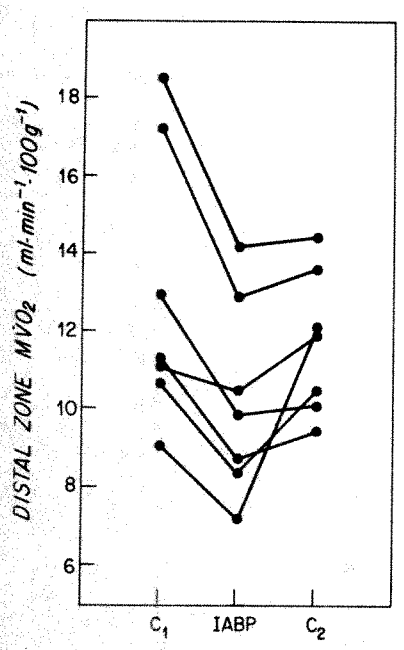

FIGURE 3. Individual responses to balloon pumping (IABP) of distal zone regional myocardial oxygen consumption (MVO_2) for each of the 9 animals. A decline in MVO_2 in response to IABP occurred in each animal. C_1 and C_2 = control 1 and control 2 periods, respectively; MVO_2 = (arterial − anterior interventricular vein O_2 content difference) × (transmural distal zone blood flow).

pigs (1.02 ± 0.09, $p < 0.001$) studied under similar conditions in our laboratory in the course of other experiments (unpublished observations).

Effects of intraaortic balloon counterpulsation on regional myocardial function (n = 3) animals with severe coronary artery stenosis) (Table V): Mean velocity of circumferential fiber shortening improved versus control during balloon pumping in 2 of the 3 animals and remained unchanged in the 3rd. Each animal demonstrated a reduction (versus control) in both rate pressure product and regional myocardial oxygen consumption in response to arterial counterpulsation. Similarly, epicardial blood flow distal to the stenosis declined versus control during arterial counterpulsation in each animal. Distal zone endocardial blood flow also declined versus control during balloon pumping in animals but improved in the 3rd. Circumflex zone endocardial and epicardial flows declined versus control in each animal in response to balloon pumping. Regional systolic function improved versus control in the circumflex zone in response to counterpulsation in 2 animals. Circumflex zone function could not be determined in the 3rd animal because the length sensors in this region failed to function properly at the time of the study.

Discussion

Critique of methods: For the preparation to be useful in understanding the mechanism by which arterial counterpulsation ameliorates myocardial ischemia in the setting of a severely stenosed but patent coronary artery, it is necessary to establish that regional ischemia was present distal to the stenosis. In this regard data obtained in 2 animals in which regional flow and function were measured before and after insertion of the stenosis demonstrated that the stenosis caused a decline in regional blood flow and impairment of regional systolic function, that is, functional evidence of ischemia. Furthermore, studies by other investigators[24,25] show that even modest decreases in regional subendocardial blood flow are capable of impairing endocardial as well as epicardial fiber shortening and hence causing functional evidence of ischemia. In the primary group of 9 animals used in this study the distal zone endocardial/epicardial flow ratio was less than unity and significantly less than that of the circumflex zone. Moreover, the absolute value of the distal zone endocardial/epicardial ratio under control condition (0.92 ± 0.12) undoubtedly would have been lower if we had sectioned the hearts into 4 layers and compared the innermost endocardial layer with the outermost epicardial layer as other investigators have done.[24,26] In addition, distal zone endocardial flow was reduced to a mean of 67% of circumflex zone endocardial flow under control conditions whereas distal zone epicardial flow was reduced to a mean of 81% of circumflex zone epicardial flow (Table II). Accordingly, it is clear at a minimum that the distal zone endocardium was underperfused at rest in the primary group of 9 animals used in the study.

It is reasonable to assume that regional myocardial ischemia (manifested by impaired systolic function) also was present because (1) hypoperfusion of the endocardium is known to impair regional function, and (2) studies in the smaller group of 2 animals demonstrated deterioration of regional function after placement of the stenosis. In addition, it should be recalled that most patients with unstable angina pectoris usually manifest subendocardial rather than transmural myocardial ischemia,[1–4] an observation that also supports the relevance of the animal model used in this study to the clinical problem of unstable angina pectoris in man. Finally, it should be emphasized that the model employed may not be relevant to the patient with myocardial ischemia complicated by cardiogenic shock. Intraaortic balloon pumping may relieve ischemia and improve ventricular performance in such patients by a different mechanism (such as an increase in coronary perfusion pressure with a subsequent increase in myocardial blood flow[5]) from that which applies to patients with ischemia but normal arterial pressure and cardiac output (see later).

Analysis of results: The purpose of this study was to determine the effect of intraaortic balloon pumping on regional myocardial blood flow distal to a severe coronary artery stenosis. Experiments were performed in a controlled, closed chest, conscious animal model with at least moderate regional ischemia in order to better understand the mechanism(s) by which this intervention ameliorates myocardial ischemia in patients with unstable angina pectoris. We observed that arterial

counterpulsation produced a consistent reduction in tension time index and rate pressure product along with a significant increase in mean diastolic pressure in the aorta. The magnitude of these changes was comparable to those achieved by previous investigators in studies conducted in both canine preparations[5–8,15] and man.[3,4] Despite the fact that aortic mean diastolic pressure was successfully augmented by arterial counterpulsation, no change in mean diastolic or overall mean distal coronary artery pressure occurred for the primary group as a whole (n = 9) although 5 of 9 animals did exhibit an increase in mean diastolic pressure distal to the stenosis. Likewise, myocardial blood flow distal to the stenosis was not increased by balloon pumping. Indeed, epicardial blood flow declined significantly distal to the stenosis. Furthermore, a strong correlation was observed between the rate pressure product and regional myocardial oxygen consumption distal to the stenosis. Thus, the distal coronary bed appeared to autoregulate in response to a decrease in myocardial oxygen demand. Accordingly, distal zone blood flow failed to increase with balloon pumping not only because distal coronary pressure failed to increase in some cases but also because autoregulation of the distal coronary bed occurred.

Analysis of distal zone endocardial and epicardial blood flow responses to balloon pumping in the 5 animals in which an increase in distal coronary mean diastolic pressure occurred supports the hypothesis that autoregulation of blood flow occurred in the distal zone. Thus, an actual decrease in endocardial blood flow was observed during balloon pumping in 3 of these animals (Table VI) despite the increase in distal coronary mean diastolic pressure in all. The increments (versus control) in endocardial blood flow in 2 of the animals (2 and 4%, respectively) were small in comparison with the associated increments in distal mean diastolic pressure (16 and 21%, respectively). Furthermore, in all 5 animals distal zone epicardial blood flow decreased (versus control levels) during arterial counterpulsation. Finally, oxygen extraction by the myocardium distal to the stenosis declined in response to arterial counterpulsation (Table III), an observation that also supports the hypothesis that the distal zone autoregulated its blood flow in response to a reduction in myocardial oxygen demand.

We recognize that a decline in myocardial blood flow and oxygen consumption in the distal zone during arterial counterpulsation could just as well have been caused by a deterioration in regional myocardial function or a decrease in contractility, or both. A reflexly mediated decline in myocardial contractility occurs in dogs during balloon pumping.[7,8] However, because reflex withdrawal of sympathetic tone is thought to underly this response to arterial counterpulsation,[8] this mechanism is probably not applicable to the present study because all animals were pretreated with propranolol (1 to 2 mg·kg^{-1}) before institution of balloon pumping. It also should be noted that the reduction in maximal positive left ventricular dP/dT observed during arterial counterpulsation may simply reflect the associated decrease in left ventricular systolic pressure[27] and does not necessarily imply a decline in contractility. A deterioration in regional myocardial function with arterial counterpulsation also seems unlikely because studies in animals[28] and man[2] indicate that balloon pumping improves regional function in ischemic (as opposed to infarcted) myocardium.

In the present study balloon counterpulsation also improved regional systolic function in the 3 animals studied with ultrasonic length sensors. A decline in regional myocardial oxygen consumption during balloon pumping was measured in each of these 3 animals. Because the bulk of oxygen used by the working heart is consumed in the generation of tension with relatively little additional cost accruing to fiber shortening,[29] it is quite possible that function (defined as fiber shortening) could improve at the same time that oxygen consumption declines if afterload also is reduced (as it is with balloon pumping). Accordingly, the most likely explanation for the observed tendency for blood flow and oxygen consumption to decline in response to arterial counterpulsation is related to the tendency of the distal zone to autoregulate its blood flow in response to a reduction in oxygen demand. However, it should be emphasized that the reduction in myocardial oxygen

demand is most likely caused by systolic unloading of the ventricle rather than by depression of contractility or impairment of systolic function.

Implications: The results of this investigation demonstrate that arterial counterpulsation effectively reduces myocardial oxygen demand by means of afterload reduction but generally does not improve myocardial blood flow distal to a severe coronary stenosis. Failure of balloon pumping to increase regional blood flow distal to a severe stenosis is probably the result of (1) failure in some cases to augment mean diastolic pressure distal to the stenosis, and (2) the tendency of the distal coronary circulation to exhibit autoregulation in response to a reduction in myocardial oxygen demand. Accordingly, the data support the hypothesis that arterial counterpulsation ameliorates myocardial ischemia in the setting of a severely stenosed but patent coronary artery primarily by reducing myocardial oxygen demand rather than by increasing oxygen supply.

Detection of Ischemic Myocardium in Vivo Through the Chest Wall By Quantitative Ultrasonic Tissue Characterization

RANDOLPH D. COHEN, MD, JACK G. MOTTLEY, MA, JAMES G. MILLER, PhD, PETER B. KURNIK, MD, and BURTON E. SOBEL, MD

Quantitative analysis of ultrasound offers a potentially valuable method for noninvasive differentiation of specific types of cardiac disease and for assessment of their severity. Clinical application necessitates quantitative measurement of the ultrasonic properties of myocardium through the chest wall. This study was designed to determine whether such measurements could be made noninvasively with the aid of conventional M mode echocardiographic guidance and to characterize the quantitative effects of intervening tissue (chest wall) on the ultrasonic signals backscattered by ischemic and normal myocardium. Frequency-dependent ultrasonic backscatter (2 to 7 MHz) from normal myocardium was measured in dogs in vivo through the closed chest with the use of M mode guidance and with the chest open, directly from the myocardium. Closed-chest and open-chest measurements were repeated after ligation of the left anterior descending coronary artery in the same animals. Closed-chest data were compensated by correcting for the average value for the slope of the attenuation-frequency function of chest wall, which was determined from measurements obtained by analysis on excised tissue. Compensated closed-chest measurements correlated with measurements obtained from the epicardial surface of the heart. The differentiation of normal from ischemic myocardium with both the closed- and open-chest measurements was consistent ($p < 0.005$). The successful differentiation of normal from ischemic myocardium by determination of quantitative backscatter through the intervening chest wall supports the concept that tissue characterization by quantitative analysis of backscattered ultrasound is a potentially useful, clinically applicable approach to noninvasive detection and differentiation of intrinsic properties of normal and diseased myocardium.

Characterization of tissue based on the quantitative analysis of its ultrasonic properties is a rapidly evolving area of echocardiography. Previous reports from our own and other laboratories[1-6] indicate that ultrasonic attenuation and backscatter are two variables with particular promise. For example, attenuation of transmitted ultrasound in vitro was found to correlate closely with myocardial ischemic injury quantified by creatine kinase depletion.

Backscatter represents ultrasonic energy reflected as the result of interactions within the tissue. It is widely employed in a qualitative fashion in clinical ultrasonic imaging systems.[7-10] In vitro, quantitative measurements of ultrasonic backscatter are significantly altered by myocardial infarction due to influences of edema formation, intravascular blood cell elements, and collagen deposition.[5,11] Cardiomyopathic changes such as those induced by doxorubicin also influence quantitative ultrasonic backscatter measured in vitro.[12] Thus, quantitative analysis of ultrasonic backscatter may permit characterization of intrinsic properties of tissue in vivo with reflected ultrasound.

Previous experiments from our laboratory have involved analysis of excised canine myocardium, isolated perfused rabbit hearts, and open-chest dogs. The time course of increases in backscatter accompanying acute myocardial infarction was measured quantitatively in

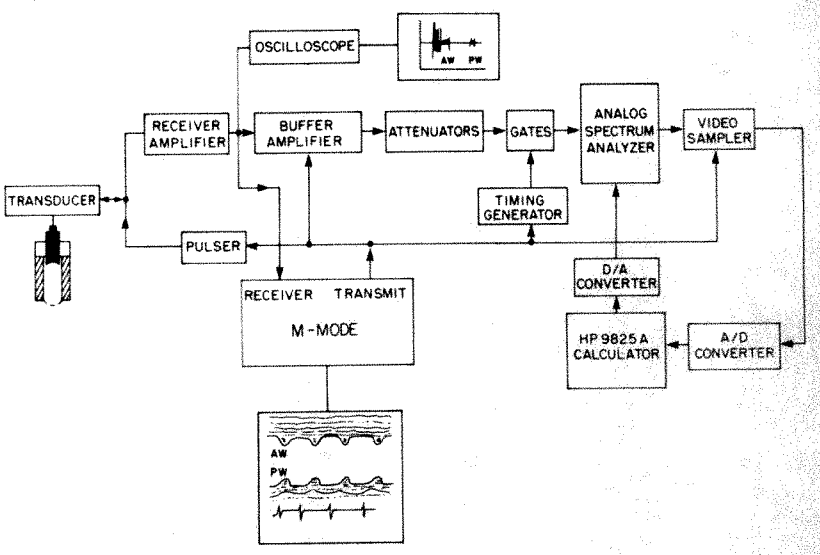

FIGURE 1. Block diagram of the data acquisition system.

an open-chest animal preparation.[5] However, clinical applications of ultrasonic tissue characterization require noninvasive measurements of ultrasound through the closed-chest wall. Unfortunately, the frequency-dependent attenuation of ultrasound by the chest wall represents a formidable obstacle to quantitative analysis of backscatter from the heart in vivo.

This study was undertaken to develop and evaluate an approach to measurement of myocardial backscatter noninvasively with the use of echocardiographic M mode guidance and to determine whether measurements of myocardial backscatter obtained from the epicardial surface of the heart in situ correlate with those obtained through the closed-chest wall in vivo when the latter are compensated for chest wall attenuation. Results indicate that myocardial backscatter can be quantified in the intact dog and used to differentiate myocardium exhibiting altered intrinsic ultrasonic properties induced by ischemia from normal tissue.

Methods

Animal preparations: Mongrel dogs were anesthetized with sodium thiopental, intubated, and ventilated with 100% oxygen and halothane. The left chest wall was shaved to provide improved transducer contact. A Smith Kline and French Ekoline M mode echocardiograph was used for guidance and to provide an electrocardiographic signal obtained with subcutaneous needle electrodes. Traditional M mode echocardiographic techniques were used for spatial localization, and quantitative analysis of ultrasound was performed on the tissue in the region of interest. The transducer with its M mode and backscatter electronics connected in parallel was placed on the surface of the skin of the left chest wall in the area of the maximal visible impulse. The transducer housing was held in position by a clamp mounted to the dog harness to prevent movement during data collection. To collect ultrasonic signals perpendicular to the myocardium and in contiguous areas, a careful search was made for sites that produced a distinct and persistent specular reflection from the endocardial surface. This practice also aided in accurate placement of the backscatter window within the boundaries of the myocardium. The M mode image was displayed on a Smith Kline and French printer as simultaneous collection of the backscattered data proceeded from multiple sites within a zone of the free wall of the left ventricle.

Acoustic windows were small in some animals, and the overall availability of sites varied from animal to animal. Separate sites were defined by a change in transducer position or orientation, resulting in an observed difference in wall motion pattern with maintenance of a distinct specular reflection from the endocardial surface. Because the beam width was narrow (approximately 3 mm in the focal zone), only minute movements of the transducer were necessary to characterize each new site.

For comparison with measurements obtained through the chest wall, additional data were collected with the transducer coupled directly to the epicardial surface. A right thoracotomy incision was made in the 5th intercostal space, the heart was suspended in a pericardial cradle, and backscatter measurements were taken from the area of the left ventricle adjacent to the left chest wall which comprised myocardium supplied by the left anterior descending coronary artery (LAD). Subsequently, lidocaine was administered as a 100 mg bolus to diminish ventricular arrhythmia, and the LAD was ligated immediately distal to the 1st diagonal branch. Two to 4 hours later backscatter measurements were taken from multiple sites within the ischemic region with the transducer coupled directly to the epicardial surface. The pericardium was then partially closed, and the right thoracotomy incision was repaired surgically. The dog was again suspended in the harness. Repeat measurements were obtained noninvasively from the untouched left chest wall with the use of M mode guidance as previously described. The ischemic zone was readily detectable based on hypokinesia or akinesia.

Ultrasonic methods: A block diagram of the data acquisition system is shown in Figure 1. The transmit pulse from a conventional M mode unit was used to trigger a separate pulser and all timing circuits. The pulser (Metrotek model MP 215) sent a short (less than 500 ns), high voltage impulse to a broadband transducer (Panametrics V309, 1.2 cm diameter, 5 MHz center frequency, and 5 cm focal length) which produced an ultrasonic pulse of wide bandwidth.

The transducer was mounted in a Plexiglas holder which was filled with degassed, distilled water and capped by a flexible latex tip. The water column served as an acoustic delay line and facilitated placement of the tissue of interest within the focal zone of the transducer. Closed-chest measurements were made with the tip placed against the skin after applica-

tion of acoustic gel. Open-chest measurements were taken with the tip applied directly to the epicardial surface.

The backscattered signal was amplified (Metrotek MR 101, 40 dB nominal gain) and then split with 1 portion returning to the M mode receiver port. The other portion of the signal was buffered, and a 4 to 6 μs portion of the signal arising from the anterior wall was gated into an analog spectrum analyzer. The center frequency of the spectrum analyzer was under computer control and swept from 2 to 7 MHz in 500 kHz steps (analyzer bandwidth 300 kHz).

The spectrum analyzer output was integrated with a 30 μs time-constant to sum over the entire gate, and then sampled and fed into an analog to digital converter. The computer (Hewlett-Packard 9825A) sampled the converted signal at a single frequency 200 times over 2 seconds and averaged all values to encompass several heart cycles before setting the analyzer to the next frequency. Raw data spectra were recorded on magnetic tape for subsequent processing. Simultaneous M mode recordings were made and chest wall thickness was estimated from the M mode and radio frequency (RF) tracing.

Immediately after completion of data collection the transducer was immersed in a degassed water bath and a planar stainless steel reflector (employed for calibration) placed at a distance corresponding to that of the tissue analyzed previously. Reference spectra with selected amounts of electronic attenuation were recorded for calibration purposes. During processing, the data spectra were compared with the reference values, and the spectra were reduced to signal magnitude relative to the reflector expressed in decibels (dB).

The chest wall attenuation data were collected from a separate set of animals with the use of a minicomputer-based acquisition and analysis system. Specimens of chest wall were sutured to a Plexiglas holder and immersed in a bath of degassed sodium citrate solution at a normal osmotic concentration. Narrow band pulses of 4 μs duration with center frequencies under computer control over the range 3 to 6.5 MHz were launched from a commercial wideband piezoelectric transducer (Panametrics V309, 5 MHz center frequency, 0.5 inch diameter, and 10 cm focal length) and were received with an acoustoelectric receiver, constructed in our laboratory to avoid phase cancellation errors (aperture 1.2 cm^2).[13,14] Substitution measurements were obtained, and the signal strength, as a function of frequency, was computed. The average slope of the attenuation ($\overline{\alpha_I}$) as a function of frequency was found to be 1.8 ± 0.4 dB/cm/MHz (mean ± standard deviation, 5 dogs, 111 sites).

The backscatter transfer function of a tissue is represented as S(f), a function of the frequency (f). If this tissue is insonified through an intervening layer of thickness D and attenuation coefficient $\alpha_I(f)$, then the ultrasonic intensity received by the transducer in a pulse echo experiment is

$$V_{tissue}(f) = P(f)S(f)e^{-2D\alpha_I(f)} \quad (1)$$

where P(f) is the spectrum of the incident pulse and the response of the electronic system. If the tissue is replaced by a planar, nearly perfect reflector, a reference signal is obtained:

$$V_{ref} = P(f) \quad (2)$$

Dividing $V_{tissue}(f)$ by $V_{ref}(f)$ yields the relative spectrum:

$$V(f) = S(f)e^{-2D\alpha(f)} \quad (3)$$

(In open-chest measurements D = 0, and thus the transfer function S(f) is obtained directly.)

In each experiment spectra were obtained from different sites and averaged. At each site the chest wall thickness D was estimated echocardiographically. The individual estimates were used to obtain an average thickness ($\overline{D}$) for each animal. This estimate of thickness and the average attenuation coefficient measured as described above, $\overline{\alpha_I(f)}$, were used to obtain a compensation factor $e^{2\overline{D}\overline{\alpha_I(f)}}$ for each animal. Thus, closed-chest spectra were compensated for the frequency-dependent attenuation of chest wall to obtain an estimate, $S_{est}(f)$, of the backscatter transfer function of myocardium:

$$S_{est}(f) = S(f)\, e^{-2D\alpha_I(f)}e^{2\overline{D}\overline{\alpha_I(f)}} \approx S(f) \quad (4)$$

Statistical methods: Comparison of data from open- and closed-chest conditions was performed with chi-square analysis. Separation of normal and ischemic myocardium was evaluated with student's t test.

Results

Upright positioning of the animals proved to provide the most consistent and repeatable echocardiograms. Only animals from whom pre- and postinfarct echoes could be obtained are reported. Some of the problems leading to failure to obtain both sets of measurements in other dogs included anesthesia- or ligation-induced arrhythmias including ventricular fibrillation and lung interposition blocking acoustic windows.

Contraction of the anterior wall detectable by echocardiography was angle-dependent before and after coronary artery ligation. Diminished wall motion may have been due to halothane, along with the bradycardia often seen. However, neither altered wall motion nor systolic wall thinning hampered the placement of the backscatter gate, because gate position was dependent on the location of the specular reflection from the endocardial surface. The specular reflection was used to assure approximately perpendicular orientation of the tissue to the insonifying beam.

Representative samples of M mode echocardiograms from normal and ischemic myocardium are shown in Figure 2. The top panel displays wall motion of normal, anterior left ventricular myocardium. The bottom panel illustrates lack of motion of the anterior wall induced by ischemia. The ischemic anterior wall akinesia, compensatory increased motion of the posterior wall, and the observed electrocardiographic changes are consistent with myocardial infarction.

Figure 3 displays the average backscatter from normal myocardium in 5 dogs as a function of frequency from 2 to 7 MHz. The magnitude is displayed in dB relative to the reflections from a stainless steel reflector, the standard by which all signals were calibrated. The top panel of Figure 3 depicts measurements with open- and closed-chest conditions without compensation for chest wall attenuation. The frequency-dependent differences between these 2 spectra are caused by attenuation of the chest wall. The bottom panel of Figure 3 shows virtual superimposition of results when closed-chest measurements were compensated for chest wall attenuation. Figure 4 shows comparable results from ischemic myocardium in the same 5 animals. The measurements obtained under closed- and open-chest conditions correspond closely when the closed-chest

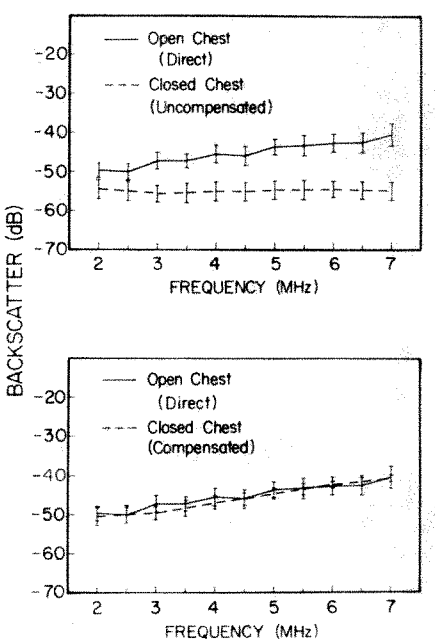

FIGURE 4. Backscatter as a function of frequency obtained from ischemic canine myocardium under open- and closed-chest conditions without compensation for chest wall attenuation (n = 5 dogs) (**top panel**). Corresponding data with closed-chest values compensated based on chest wall attenuation (**bottom panel**).

measurements are compensated for the attenuation of chest wall. The measurements from ischemic tissue demonstrate increased backscatter in comparison with results from normal zones.

In Figure 5, the closed-chest estimates of backscatter are correlated with the open-chest measurements at the same frequency and from the same animals with a line of identity shown for reference. In the top panel, the uncompensated backscatter values fall below the line of identity ($\chi^2 = 8.33$, n = 5 dogs, 55 data points). In the bottom panel, which depicts results after compensation for chest wall attenuation, values distribute well along the line of identity ($\chi^2 = 0.77$). Similar results from ischemic myocardium are shown in Figure 6, with corresponding values of $\chi^2 = 12.05$ and 1.06 (n = 5 dogs, 55 data points) for uncompensated and compensated values, respectively.

The spectral data were averaged over frequency to obtain an index denoted integrated backscatter. In Figure 7, compensated closed-chest measurements are shown (normal −49.4 ± 0.34 dB, 90 sites; ischemic −45.8 ± 0.33 dB, 105 sites, mean ± standard error [SE], n = 5 dogs). These compensated values correlate with direct epicardial measurements (normal −50.8 ± 0.41 dB, 48 sites; ischemic −45.3 ± 0.46 dB, 48 sites, mean ± SE, n = 5 dogs). The separation of normal from ischemic myocardium for both the closed- and open-chest measurements was significant ($p < 0.005$) and comprised a difference in backscattered energy of more than 200%.

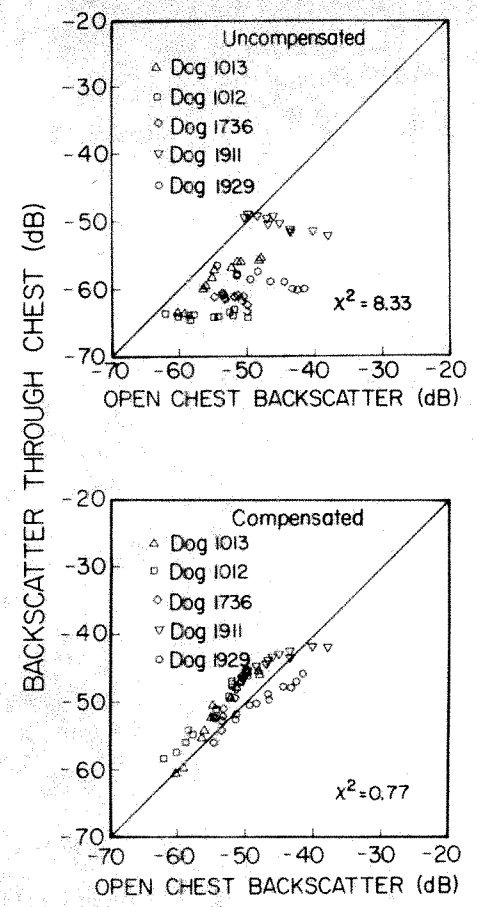

FIGURE 5. Uncompensated closed-chest backscatter from normal myocardium. The values fall substantially below a line of identity yielding a chi-square value of 8.33 **(top panel)**. Compensated closed-chest values compared with open-chest backscatter. The data fall along a line of identity, with chi-square = 0.77 **(bottom panel)**.

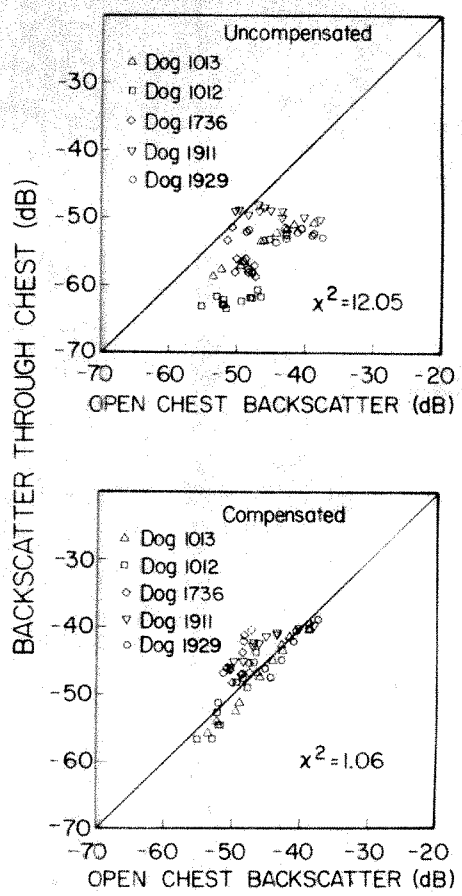

FIGURE 6. Uncompensated closed-chest backscatter from ischemic myocardium compared with open-chest backscatter. The values fall substantially below a line of identity yielding a chi-square value of 12.05 **(top panel)**. Compensated closed-chest values compared with open-chest backscatter. The data fall along a line of identity with chi-square = 1.06 **(bottom panel)**.

Discussion

Results from this study demonstrate that the quantitative analysis of ultrasonic backscatter permits noninvasive detection of myocardial structural alterations and intrinsic properties. Measurement of backscatter from normal and ischemic left ventricle through the closed chest were confirmed by open-chest data obtained from the heart in situ.

In previous studies we showed that ultrasound can be used to characterize physical properties of tissue in vitro. In zones of infarction analyzed in vitro with transmitted ultrasound, an ultrasonic index based on attenuation changed concordantly with an independent index of myocardial injury, creatine kinase depletion.[3] Subsequent experiments indicated that collagen content, measured by analysis for hydroxyproline, correlated closely with the ultrasonic index slope of attenuation with frequency.[15] Collagen deposition was found to contribute to the increased attenuation found in regions of completed myocardial infarction. In central dense regions of fibrosis associated with myocardial infarction in both dog and rabbit hearts, collagen deposition resulted in significantly increased ultrasonic backscatter.[11,15] Furthermore, perfusion of isolated rabbit hearts having zones of infarction with collagenase demonstrated that backscatter was sensitively dependent on intact collagen.[11]

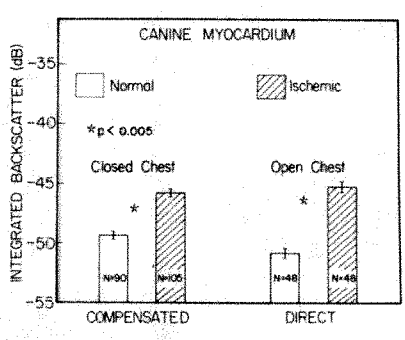

FIGURE 7. Integrated backscatter from normal and ischemic myocardium with compensated closed- and open-chest conditions ($p < 0.005$).

Backscatter was found to increase in acutely ischemic zones of open-chest dogs in vivo within 1 hour after the

onset of ischemia and to plateau at a value of 400% of control by 4 hours.[6] This increase in backscatter occurred only in regions of ischemic myocardium in which blood flow, measured with ^{141}Ce-labeled microspheres, was less than 20% of control. Thus, increased backscatter in acutely ischemic myocardium was not related linearly to flow. It appeared to depend on cellular and structural concomitants of severe ischemia. In additional experiments with perfused rabbit hearts, contributions of tissue water were implicated.[5]

The potential applicability of quantitative analysis of ultrasound for tissue characterization of the heart was explored further in vitro after induction of Adriamycin™ cardiomyopathy in rabbits. Integrated ultrasonic backscatter was increased in densely fibrotic regions and significantly, although less markedly, in myopathic regions without marked deposition of collagen.[12]

The present study was performed to determine whether the quantitative analysis of ultrasound obtained noninvasively could be used for tissue characterization in the intact dog. Difficulties in obtaining adequate acoustic windows are greater in dogs than in man, although the left ventricle in the dog is immediately adjacent to the chest wall whereas in man the right ventricle is interposed anteriorly. In many instances neither the epicardium of the anterior wall nor the posterior wall could be visualized readily. However, the identification of the specular reflection from the endocardium was found to be a useful landmark. When a large endocardial reflection was present, the gate for backscatter measurement could be placed so that it remained within the myocardium throughout the cardiac cycle. The spectral displays of Figures 3 and 4 show the separation of curves due to attenuation of the chest wall. The frequency dependence of the attenuation of the chest wall is evident from the greater separation of the curves at higher frequencies. The compensation factor, which also depends on chest wall thickness, showed only minor variation from animal to animal. The pericardium, even with associated fatty tissue, had insignificant effects on attenuation.

The spectral curves were converted to integrated backscatter by computing the area under the curve. Figure 7 shows the difference in integrated backscatter between normal and ischemic myocardium with closed- and open-chest measurements. Separation of values from ischemic and normal myocardium was slightly greater with the open-chest data probably because of factors influencing attenuation of sound by the intervening tissue, variability of chest wall thickness, and gate and focal zone position.

Despite these limitations, the present results suggest that myocardial acoustic properties can be quantified noninvasively and potentially clinically by adaptation of M mode and 2 dimensional echocardiographic techniques. Calculation of chest wall attenuation from reflected signals in real time will be necessary for studies in patients. Although attenuation is an intrinsic property of tissue, estimates obtained based on reflected ultrasound exhibit substantial variability. Aspects of the intervening tissue problem have been addressed by Reid[16] and others[17] who have considered several levels of required compensation and evaluated the advantages of generalized substitution techniques to yield both relative and absolute measurements. On the basis of previous results from our own and other laboratories[18] plus the experience gained in the studies reported here, clinically applicable methods for attenuation compensation in man appear to be quite feasible.

The diagnostic detection and differentiation of myocardial disease noninvasively based on quantitative ultrasonic characterization of tissue is a promising application of clinical ultrasonography. It may permit improved detection and differentiation of cardiomyopathies, cardiac tumors, and sequelae of ischemic events, as well as their responses to prophylactic or therapeutic interventions.

Increased R-Wave Amplitude Induced by Acute Myocardial Ischemia in the Dog: A Predictor of Malignant Ventricular Arrhythmias

DANIEL DAVID, MD,* ERIC L. MICHELSON, MD,† MASAHITO NAITO, MD, MARK SCHAFFENBURG, and LEONARD S. DREIFUS, MD

The ability of an increase of 25% or greater in the sum of R-wave amplitudes in leads X, Y, Z, L_2, and V_5 to predict the occurrence of malignant ventricular arrhythmias (10 or more ventricular premature beats/min, ventricular tachycardia [5 or more consecutive premature beats], and/or fibrillation) was evaluated in 17 dogs during experimental acute myocardial ischemia. Each dog underwent a 15 minute ligation of the left anterior descending coronary artery followed by reperfusion and after recovery, 2 hours later, a 15 minute ligation of the circumflex coronary artery. During ligation of the left anterior descending coronary artery, 12 of 17 dogs (71%) showed no R-wave increase and no arrhythmias (true-negative response). In 5 (29%) of 17 dogs malignant ventricular arrhythmias developed: 2 of 5 (40%) dogs with arrhythmias had a concomitant R-wave increase (true-positive response), and 3 of 5 (60%) with arrhythmias had a less than 25% increase in R-wave amplitude (false-negative results). During circumflex coronary artery ligation, 13 of 17 (76%) dogs showed both R-wave increases and arrhythmias (true-positive response). Four (24%) of 17 dogs had no arrhythmias: 3 of 4 (75%) with no arrhythmias also had a less than 25% increase in R-wave amplitude (true-negative response), whereas 1 of 4 (25%) dogs with no arrhythmias had an increase in R-wave amplitude (false-positive response). In dogs with both arrhythmias and R-wave increases, R-wave changes preceded the onset of arrhythmias by a mean (± standard deviation) of 1 minute 27 seconds (±43 seconds). Overall, R-wave increases were highly sensitive (83%), specific (94%), and predictive (94%) for the occurrence of malignant ventricular arrhythmias during experimental acute myocardial ischemia.

R-wave amplitude increases have been observed in man during acute myocardial ischemia induced by both exercise and rapid atrial pacing.[1–9] Alterations in R-wave amplitude were also recorded in dogs after acute ligation of a major coronary artery[10] and may be seen as early as 10 seconds from the onset of ischemia.[11] After experimental canine coronary artery occlusion, changes in intramyocardial conduction were a major determinant of alterations in R-wave amplitude.[12] In other studies,[12–19] delays in intramyocardial conduction during the acute phase of myocardial ischemia were also closely associated with malignant ventricular arrhythmias. Conceivably, therefore, ischemia-induced alterations in R-wave amplitude might predict malignant ventricular arrhythmias. Thus, the present study was designed to determine the relation between R-wave amplitude alterations and the occurrence of malignant ventricular arrhythmias during the acute phase of experimental myocardial ischemia in a canine model.

bolus infusions as indicated to maintain effective anesthesia). After intubation and ventilation with room air through a Harvard respirator, mid-sternotomy was performed, the pericardium opened, and the heart suspended in a pericardial cradle. The left anterior descending coronary artery was isolated approximately 1 to 3 cm beyond its origin from the left main stem, distal to the anterior septal artery and the first diagonal branch. Predictably, with our methods, occlusion at this site resulted in a relatively small area of ischemia in the canine myocardium. A snare ligature was placed around the artery for subsequent ligation. The left circumflex coronary artery was isolated approximately 1 to 2 cm from its origin and proximal to all branches, and a snare ligature was placed around the artery for subsequent ligation. Electrocardiographic leads L_2 and V_5 and Frank orthogonal leads X, Y, and Z were recorded throughout the experiment. The animal's limbs were restrained and their position was kept constant throughout the experiment to avoid electrocardiographic distortion related to positional changes.[20] The electrocardiogram was recorded by means of an 8 channel recorder (Hewlett Packard model 4578A) with the recording frequency set between 0.5 and 200 Hz. Data were also recorded continuously on an 8 channel FM tape recorder (Hewlett Packard model 3968A) for subsequent data reproduction and analysis.

Experimental protocol: In each dog, a 1 stage temporary (15 minute) ligation of the left anterior descending coronary artery was performed; release of the occlusion was followed by a 2 hour recovery period, after which a 1 stage temporary (15 minute) ligation of the left circumflex coronary artery was carried out, again followed by release of the occlusion. This sequence was chosen to enable us to perform both types of ligation in each dog. In preliminary studies the sequence of ligations was reversed (circumflex before left anterior descending coronary artery) in alternate animals. Although the results were similar, a large number of dogs were lost because of the high incidence of refractory ventricular fibrillation during circumflex coronary artery ligation, and therefore this protocol was abandoned.

In those animals in which ventricular fibrillation occurred during ligation of the left anterior descending artery, the artery was immediately reperfused and defibrillation accomplished with 1 or 2 countershocks of 10 and 40 W·s, respectively. After a 2 hour recovery period, the circumflex ligation procedure was performed.

Measurements and definitions: R-wave amplitude was measured from the P-R segment (zero level reference) to the peak of the R wave in leads L_2, V_5, X, and Y and to the nadir of the Q wave in lead Z. These measurements were performed at 15 second intervals throughout the ligation period starting 5 minutes before ligation. Each data point represented a mean of 10 consecutive beats to negate respiratory influences on R-wave amplitude. R-wave amplitudes were measured in all 5 recorded leads and summed arithmetically (ΣR). All R-wave amplitude data in the text and tables represent summed data. To facilitate clinical correlations the sum of the R waves in leads L_2 and V_5 ($\Sigma R_{L2,V5}$) was calculated separately and correlated with the sum of R wave amplitudes in all 5 leads. An increase of 25% in R-wave amplitude was regarded as a positive response, a change that could be discriminated reproducibly without significant intra- or interobserver variability.

On the basis of previous coronary occlusion studies in our laboratory, malignant ventricular arrhythmias were defined prospectively as the occurrence of 1 or more of the following: 10 or more ventricular premature beats/min, ventricular tachycardia (5 or more consecutive ventricular premature beats), and ventricular fibrillation. In analyzing our data, dogs classified as having "no malignant arrhythmias" had either no premature ventricular beats or only 1 to 2 premature beats/min.

Statistical analysis: To evaluate the sensitivity, specificity, and predictive value of the observations made in this study the following formulas were used[21]: Sensitivity = true positives/(true positives + false negatives) ×100; Specificity = true negatives/(true negatives + false positives) ×100; Predictive value = true positives/(true positives + false positives) ×100. All data presented in the text with respect to the time course of ventricular arrhythmias represent a mean ± standard deviation.

Results

Left anterior descending coronary artery ligations: No malignant ventricular arrhythmias were observed in 12 (71%) of the 17 dogs during the 15 minutes after ligation of the left anterior descending coronary artery (Table I). In each of these 12 animals (100%) the increases in both ΣR and $\Sigma R_{L2,V5}$ were less than 25% above baseline (true negatives, Fig. 1). In the remaining 5 of 17 dogs (29%) malignant ventricular arrhythmias (4 ventricular fibrillation, 1 ventricular tachycardia) occurred after ligation of the left anterior descending coronary artery. These arrhythmias occurred a mean of 6 minutes 17 seconds (±1 minute 37 seconds) after ligation. In 2 (40%) of these 5 dogs both ΣR as well as $\Sigma R_{L2,V5}$ increased more than 25% above baseline (true positives) and preceded the onset of malignant ventricular arrhythmias in both cases by a mean of 1 minute 18 seconds (±38 seconds). In 3 of 5 (60%) animals with

TABLE II Sensitivity, Specificity, and Predictive Value of R-Wave Amplitude Changes for the Occurrence of Malignant Ventricular Arrhythmias During Acute Ischemia

	Cx Ligation	LAD Ligation	Both Ligations
Sensitivity (%)	100	40	83
Specificity (%)	75	100	94
Predictive value (%)	93	100	94

Cx = circumflex coronary artery; LAD = left anterior descending coronary artery.

arrhythmias no significant changes (less than 25%) in either ΣR or $\Sigma R_{L2,V5}$ were observed (false negatives).

Left circumflex coronary artery ligations: Malignant ventricular arrhythmias were observed in 13 (76%) of 17 dogs after ligation of the left circumflex coronary artery (10 ventricular fibrillation, 2 ventricular tachycardia, and 1 frequent premature ventricular beats) (Table I). These arrhythmias occurred at a mean of 4 minutes 35 seconds (±2 minutes 15 seconds) after ligation. All 13 dogs (100%) with arrhythmias had an increase of 25% or greater in both ΣR and $\Sigma R_{L2,V5}$ (true positives) (Fig. 2). Increases in ΣR and $\Sigma R_{L2,V5}$ preceded the onset of malignant ventricular arrhythmias in each case, by a mean of 1 minute 37 seconds (±43 seconds). In 4 of 17 dogs (24%) no malignant ventricular arrhythmias occurred, and 3 (75%) of these 4 had less than 25% increases in both ΣR and $\Sigma R_{L2,V5}$ (true negatives), whereas in 1 dog (25%) both ΣR and $\Sigma R_{L2,V5}$ increased 25% or greater (false positive) (Table I).

Overall, an increase of 25% or greater in ΣR during the period of acute myocardial ischemia after left anterior descending coronary artery ligation showed a sensitivity of 40%, specificity of 100%, and a predictive value of 100% with respect to the occurrence of malignant ventricular arrhythmias (Table II). In comparison, an increase of 25% or greater in ΣR during circumflex ligation showed a sensitivity of 100%, specificity of 75%, and a predictive value of 93% with respect to the occurrence of acute malignant ventricular arrhythmias. When the data for both ligation procedures were combined, ΣR amplitude increases showed an overall sensitivity of 83%, specificity of 94%, and a predictive value of 94% in predicting the occurrence of acute ischemia-induced malignant ventricular arrhythmias. Results for $\Sigma R_{L2,V5}$ were identical to those for ΣR wave amplitude alterations with respect to sensitivity, specificity, and predictive value for malignant ventricular arrhythmias after both the left anterior descending and circumflex ligation procedures. In addition, $\Sigma R_{L2,V5}$ results were also concordant in each animal (Table II).

Discussion

R-wave amplitude increases have been observed in patients with acute myocardial ischemia induced by both exercise[1–8] and rapid atrial pacing.[9] R wave amplitude increases in the canine model of coronary artery occlusion have also been appreciated since the detailed observations of Rakita et al.[10] In experimental canine preparations, R-wave amplitude changes during acute, extensive myocardial ischemia follow a typical pattern.[11] There is an initial (onset within 10 seconds) and transient (duration 30 to 60 seconds) decrease in R-wave amplitude followed by a secondary marked and persistent increase in R-wave amplitude[11] (Fig. 2). In attempting to elucidate the pathophysiologic basis for this phenomenon, it was found that intramyocardial conduction changes rather than variations in intraven-

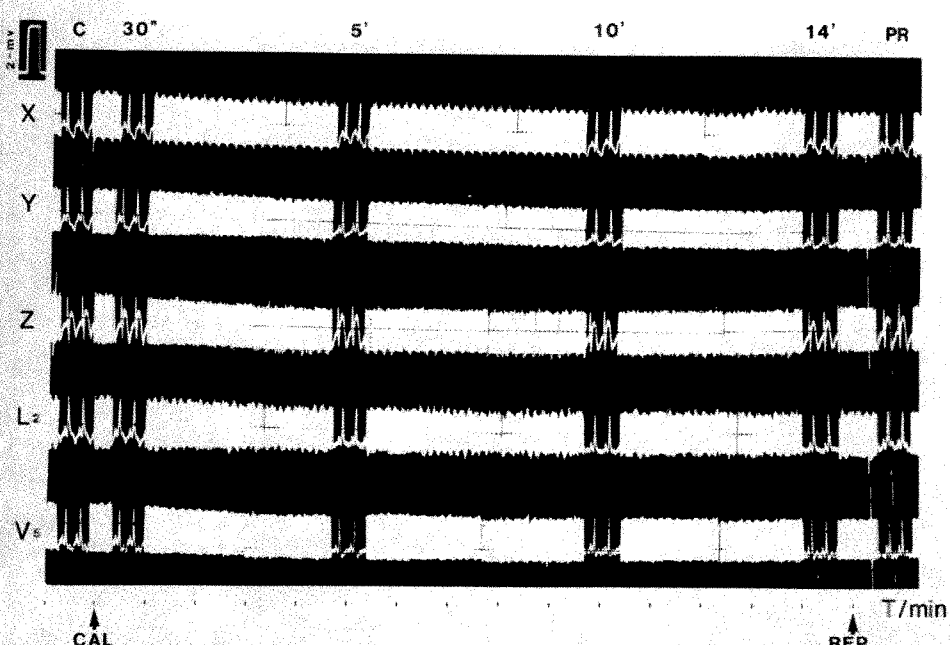

FIGURE 1. Electrocardiographic trend recording during ligation (CAL) and reperfusion (REP) of the distal left anterior descending coronary artery. Frank orthogonal leads X, Y, and Z as well as scalar leads L_2 and V_5 are demonstrated. Representative QRS complexes are shown during the control period (C), at 30 seconds, at 5, 10, and 14 minutes after coronary artery ligation, and in the immediate postreperfusion period (PR). Note that R-wave amplitude does not change significantly from control in any of these leads either after the 15 minute ligation period or during reperfusion. Correspondingly, this dog had no malignant ventricular arrhythmia.

tricular volume were the major factor determining R-wave amplitude changes during acute myocardial ischemia.[12] The initial decrease in R-wave amplitude was closely related to a transient shortening of intramyocardial conduction time (from endocardium to epicardium) observed during the first 30 to 60 seconds of acute myocardial ischemia, whereas the later and persistent increase in R-wave amplitude occurred in association with a marked delay in intramyocardial conduction.[12]

It is well established that malignant ventricular arrhythmias occur commonly during acute experimental myocardial ischemia, although their frequency is highly variable (10 to 90%).[21,22] The incidence of ventricular arrhythmias after coronary artery occlusion depends on many factors such as the vessel ligated, the method of occlusion (such as 1 stage versus 2 stage), and the site of occlusion (such as proximal versus distal); with the mass of tissue involved and the extent of preformed anastomosing collateral vessels as critical factors.[23] Previously, investigators have related the occurrence of malignant arrhythmias during acute ischemia to associated alterations and delays in local conduction.[13–19] Thus, on the basis of the association of both arrhythmias and R-wave amplitude changes with alterations in intramyocardial conduction it was of considerable interest to study the possible relation of arrhythmias and R-wave changes. Clinically, intramyocardial conduction changes cannot be measured directly. Therefore, the potential clinical importance of R-wave amplitude alterations as markers for subsequent malignant arrhythmias was considered.

The results presented in this study clearly support this assumption. The combined data from both the left anterior descending and circumflex coronary artery ligations show that R-wave amplitude increases are sensitive and specific predictors of malignant ventricular arrhythmias during the first 10 minutes of acute canine myocardial ischemia. Typically, R-wave amplitude changes preceded the occurrence of arrhythmias by a mean of approximately 1 minute 30 seconds.

The circumflex coronary artery is the dominant coronary vessel in the dog. Its proximal ligation involves a large mass of myocardium, which presumably accounts in part for the high incidence of malignant ventricular arrhythmias. Intramyocardial conduction delay and fragmentation after circumflex ligation involves a large area of myocardium which may, in turn, account for the appearance of significant R-wave amplitude changes on the surface electrocardiogram. In contrast, ligation of the mid left anterior descending coronary artery involves a smaller mass of myocardial tissue in the dog and is therefore associated with a lower incidence of malignant ventricular arrhythmias. Because intramyocardial conduction abnormalities are confined to a relatively smaller region of myocardium, they are not as readily reflected as R-wave amplitude alterations on the scalar electrocardiogram. The fact that the results of both the circumflex and left anterior descending coronary artery ligations were analyzed in each dog

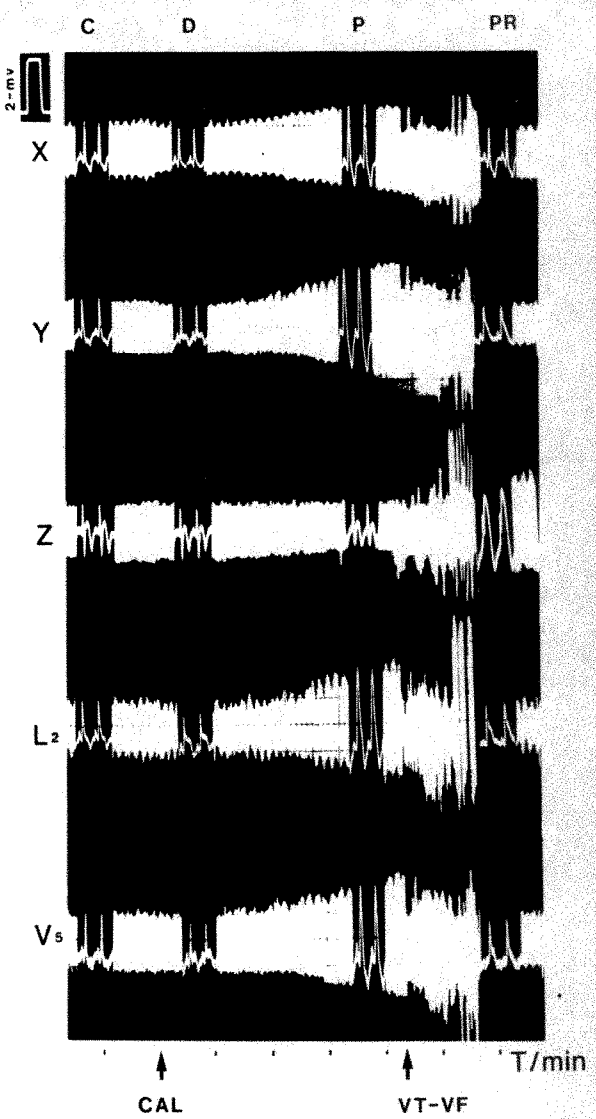

FIGURE 2. Electrocardiographic trend recording during ligation (CAL) and after reperfusion (PR) of the left circumflex coronary artery in the same dog shown in Figure 1. Frank orthogonal leads X, Y, and Z as well as scalar leads L_2 and V_5 are demonstrated. Representative QRS complexes are shown during the control period (C), 30 seconds after ligation (D), 4 minutes after ligation (P), and immediately after reperfusion and resuscitation from ventricular tachycardia (VT) followed closely by ventricular fibrillation (VF). Note that in each of the leads except Z, the R-wave amplitude shows an initial decrease at time D and subsequently a marked increase, evident at time P, immediately before the initiation of VT/VF. After reperfusion and resuscitation, R-wave amplitudes normalize, but marked S-T and T wave changes can still be detected. An increase in R-wave amplitude of 25% or greater from control is already evident more than 1 minute before the occurrence of VT-VF.

lends further support to these assumptions. These analyses are particularly relevant because differences exist in coronary artery distribution patterns between the dog and man, as already noted. Overall, R-wave amplitude changes were sensitive, specific, and predictive for the occurrence of arrhythmias when both the circumflex and left anterior descending coronary artery

ligations were considered together in our model (Table II).

Clinical implications: There is considerable interest in using noninvasive methods to identify patients at high risk for sudden cardiac death, particularly those susceptible to malignant ventricular arrhythmias. The present study suggests that increases in R-wave amplitude in association with acute ischemia may be a clinically useful marker of susceptibility to malignant arrhythmias. A recent case report[24] lends further clinical support to this hypothesis. This marker may be of major interest in patients who demonstrate marked R wave amplitude increases during exercise testing or ambulatory electrocardiographic monitoring, particularly those with critical coronary artery obstructive disease. Potentially, R-wave changes may provide a useful noninvasive means to select those patients in danger of sudden electrical death, who might then be candidates for further diagnostic and therapeutic procedures. Moreover, R-wave amplitude increases may herald the onset of malignant ventricular arrhythmias in patients with recurrent severe ischemic episodes hospitalized in the coronary care unit.

To further facilitate the potential application of our findings to the human situation, we have reported the results of R-wave amplitude increases both in 5 monitored surface electrocardiographic leads (X, Y, Z, L_2, and V_5) as well as in leads L_2 and V_5, the leads most commonly used during exercise testing. Importantly, our results indicate that R-wave amplitude increases using leads L_2 and V_5 are comparable in their predictive value to the sum of R wave amplitude increases using more elaborate monitoring systems (Table I).

In summary, in this canine model of acute myocardial ischemia, R-wave amplitude increases were highly sensitive, specific, and predictive of malignant ventricular arrhythmias. Both R-wave amplitude changes and malignant arrhythmias may be related to the marked delay in intramyocardial conduction that occurs acutely in the ischemic zone. Clinical investigation of this phenomenon should be of considerable interest in the identification of patients at increased risk for sudden death.

Baseline anginal therapy simplified

Approximately 75% of angina patients were successfully controlled on the starting dosage—one Transderm-Nitro 5

Once-daily application of Transderm-Nitro was shown to provide effective 24-hour baseline therapy in the step-care approach to angina in a survey* of over 1,000 physicians with more than 10,000 patients under treatment.

Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

For full details, please see the Prescribing Information on the next page.

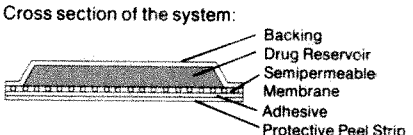
Transderm®-Nitro (nitroglycerin)
Transdermal Therapeutic System

DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring. In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.
Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

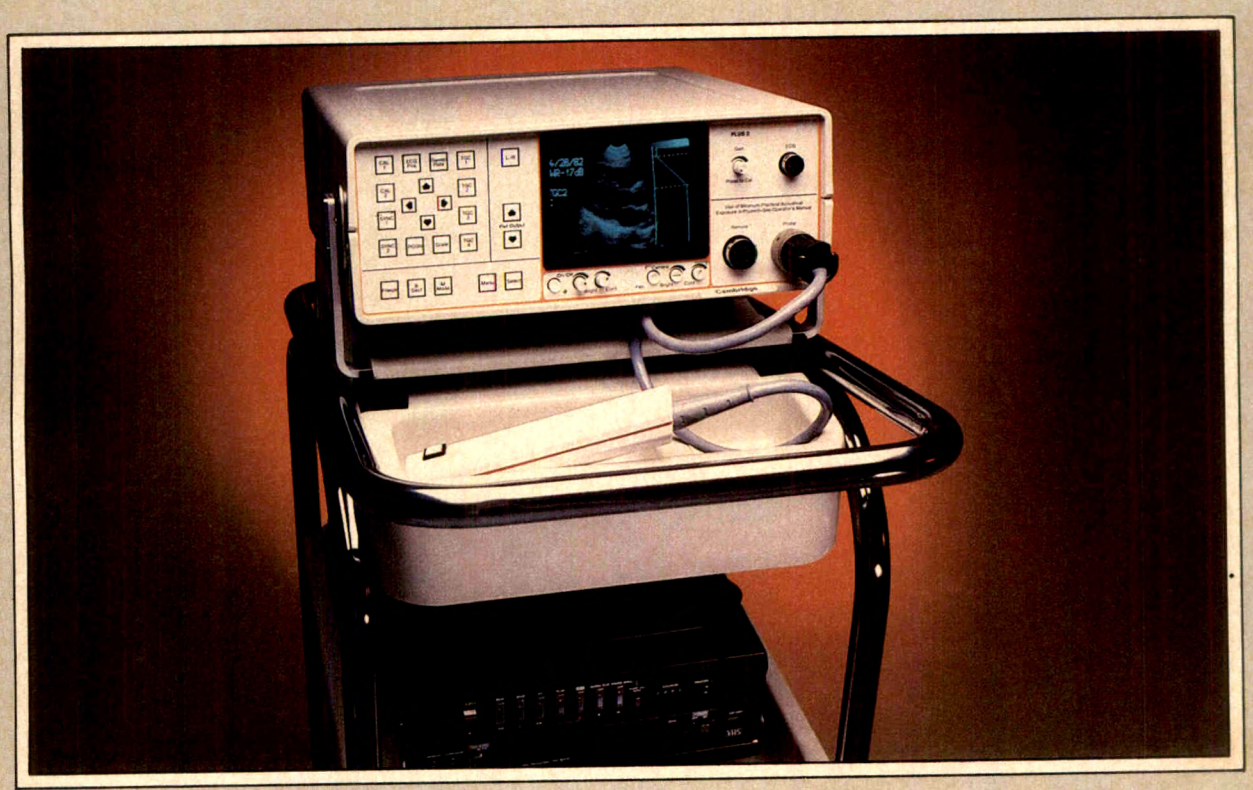
Picker International. The Source for Echocardiography.



Introducing Plus 2, A Revolutionary Portable Ultrasound System Offering High Quality M-mode And 2-D Imaging.

Now conduct echocardiography studies in your office, clinic, or CCU. Plus 2 is the only dual purpose echo system that's so portable it can go wherever you go.

Picker International has combined the latest microprocessor and ultrasound technology in a lightweight unit that is dramatically smaller and more versatile than competitive units. In clinical situations you can have this powerful diagnostic tool at bedside for your critically ill patients. And, you can easily take Plus 2 on the road with you for examination of patients in localities where equipment is not available.

Best of all, Picker International's Plus 2 portable ultrasound system is less than half the cost of other systems offering comparable diagnostic capabilities. And Plus 2 is backed by Picker International Regional Service Centers worldwide, giving you prompt, dependable service.

So come to the Source for portability in ultrasound systems. Call your Cambridge representative today. Or contact the Cambridge Division, Picker International, Inc., 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

DIABETES MELLITUS

From the publishers of the American Journal of Medicine

Jay S. Skyler, M.D.,
University of Miami School of Medicine

George F. Cahill, Jr., M.D.,
Harvard Medical School and Howard Hughes Medical Institute

60 internationally prominent contributors provide in 26 papers a comprehensive overview of the current thinking on the causes, mechanisms, treatment and complications of diabetes.

Featured topics include:

- The causes of diabetic inheritance
- Immune factors of diabetes
- Mechanisms of diabetes (The culmination of 50 years of research)
- Autoimmunity
- New understandings in the mechanisms of insulin dependent and non-dependent diabetes mellitus
- New developments in the treatment of diabetes
- Methods of monitoring blood glucose and the use of glycosylated hemoglobin
- Pharmacology of oral hypoglycemics
- Use of insulin infusion devices
- Human insulin produced by recombinant DNA technology

If it is important to you in your practice to stay up-to-date on the latest developments in Diabetes Mellitus and you need a quick reference on the topic, then this is the book for you.

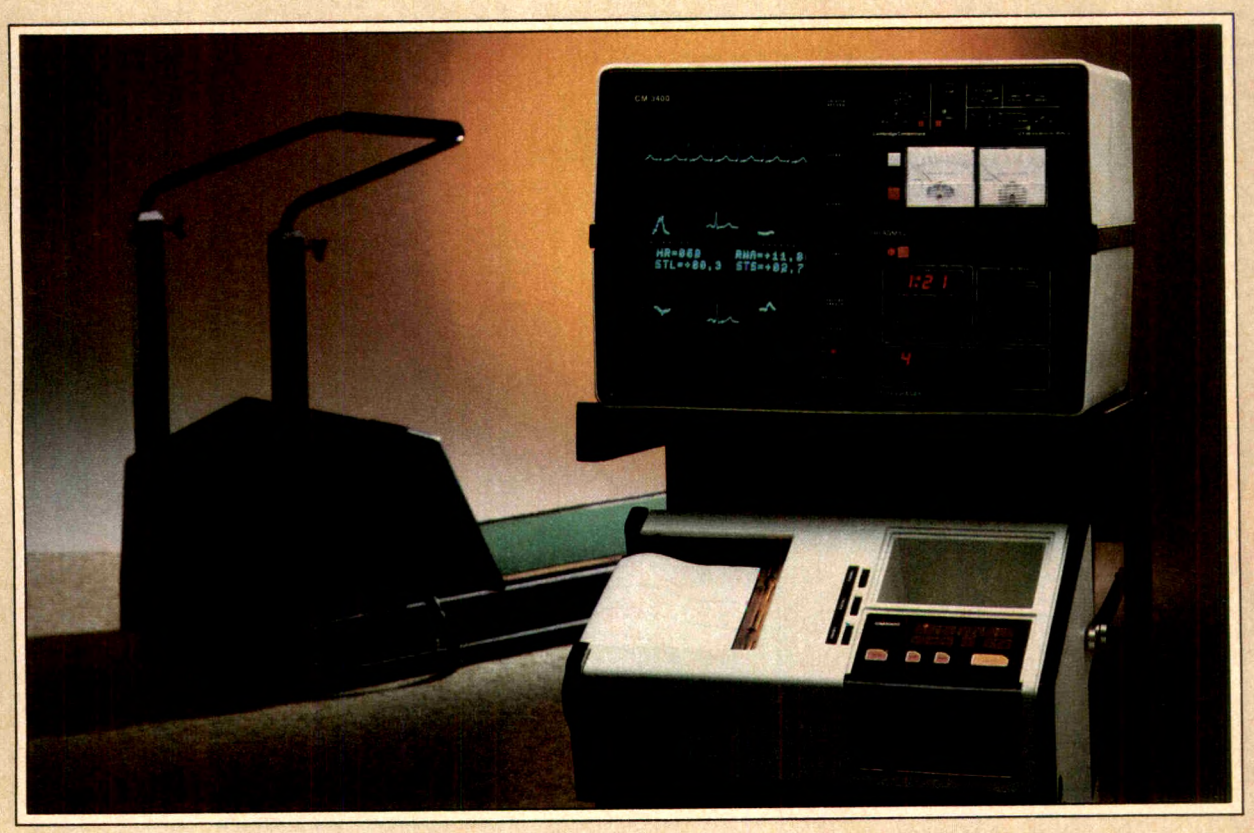
Picker International. The Source for Stress Test Systems.



Picker International's Cambridge Division is proud to announce its new computerized OBSERVER™ stress test system. Observer offers you an unbeatable combination of value and capability.

It contains all the instrumental capabilities you need to perform smooth, error-free stress tests. That includes, of course, three and twelve lead ECG write-outs, trending of ECG and computed values, signal averaging to suppress muscle artifact and noise, automatic programming of treadmill and recorder, and more.

Beyond that, OBSERVER introduces new and unique features that further enhance its value and capability. For example, real-time cursor controls enable the physician to set and reposition the ST measurement point with ease and accuracy. Or even measure ST level and slope instantaneously at several points, while the test is in progress.

OBSERVER is a great value as well. Through sound, double-duty design decisions, Picker International can offer you a fully capable system priced substantially below competitive offerings. All of which continues to make us the prime source for stress test systems.

Write or call:
Cambridge Medical Instruments Division, Picker International, Inc., 73 Spring Street, Ossining, NY 10562. Tel: (914) 941-8100.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery
Chief, Division of Thoracic and Cardiac Surgery
Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

Picker International. The Source for Electrocardiography.

Busy office practices are using the Cambridge VS-550 from Picker International to buy back time.

That's because there's not a wasted second built into this compact single channel ECG system. From standard features like automatic calibration pulses, automatic lead switching, and automatic lead marking, to perforated recording paper for the ultimate in record-mounting ease, this workhorse is designed to get you the fastest ECG's possible. And, in this case, haste does not mean waste. Because with previewing capability, you know before you record that the tracing will be satisfactory. And, thanks to its microprocessor, the VS-550 has an automatic self-test program so that you never have to repeat an ECG because you "suspect" equipment malfunction.

So, why not buy back a little time for your office by turning to the Cambridge VS-550 from Picker International. As they say, time is money.

Call your Cambridge representative today. Or contact the Cambridge Medical Instruments Division, Picker International, Inc., 73 Spring Street, Ossining, NY 10562. Tel: 914/941-8100.

PICKER INTERNATIONAL

Picker International is the source for cardiography systems.

To you, this is important.

Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

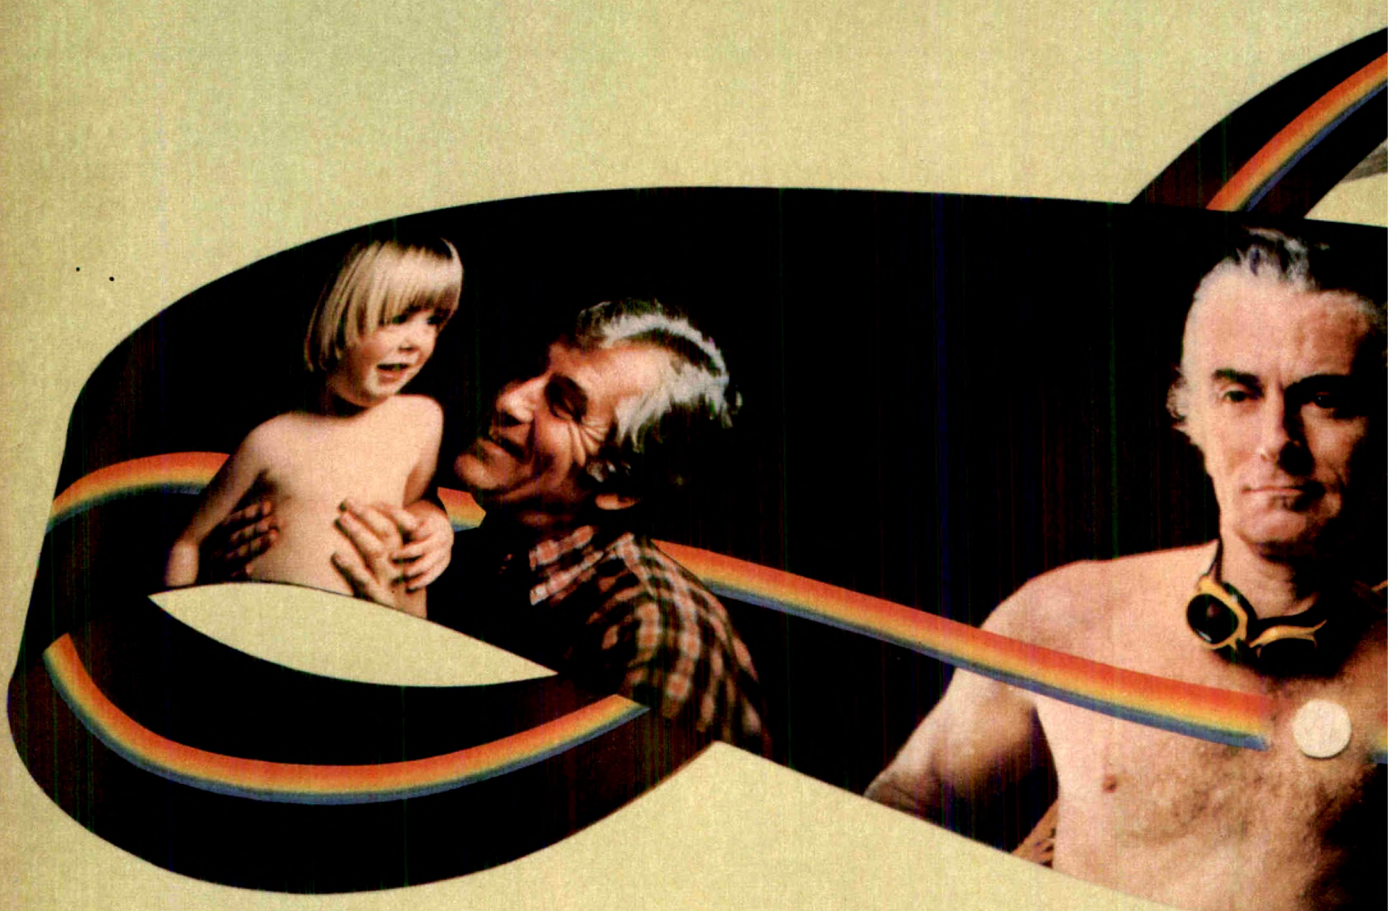
NITRODISC™

(nitroglycerin) 5-MG/24-HR; 10-MG/24-HR PAD

Continuous anginal



Contraindications for nitroglycerin include patients with increased intraocular pressure. Side effects include headache, hypotension, flushing, and dizziness. In terminating treatment, both the dosage and frequency of application must be gradually reduced during a period of four to six weeks.

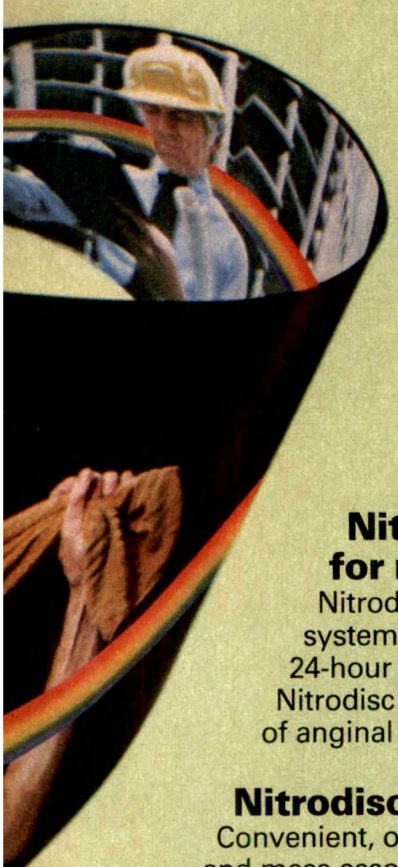
protection...q.d.

Preliminary results from a clinical study indicate 24-hour improvement in exercise capacity

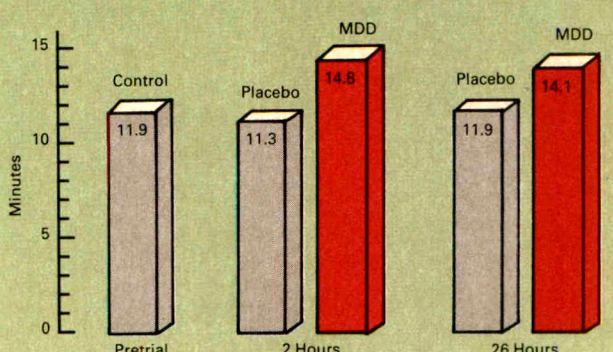
Until now, the clinically recognized benefits of a single nitrate dose have not been documented beyond 12 hours.

In a controlled study,[1] Searle's new nitroglycerin Microseal Drug Delivery™ (MDD) system provided an 18% average increase in exercise capacity 26 hours after application.[2]

In addition, the need for sublingual nitroglycerin was reduced.



Mean Exercise Duration



Nitrodisc (nitroglycerin) eliminates the need for multiple doses of long-acting oral nitrates

Nitrodisc's unique solid polymer releases nitroglycerin into the systemic circulation at a controlled and sustained rate over a 24-hour period.

Nitrodisc (nitroglycerin) is not intended for the immediate relief of anginal attacks.

Nitrodisc enhances compliance

Convenient, once-daily dosage schedule, plus the absence of bother and mess associated with nitroglycerin ointments.

Secure, waterproof adhesive allows for a complete range of daily activities.

1 The interim results presented include data on eight patients completing the protocol to date. A total of twenty patients will be included.

2 Thompson RH: Clinical use of transdermal delivery devices with nitroglycerin. Presented at the Medical Therapy for Angina in the 1980s: New Horizons Symposium, Atlanta, April 24, 1982.

In another clinical study conducted among cardiac rehabilitation participants, concomitant Nitrodisc (nitroglycerin) propranolol therapy did not demonstrate a significant improvement over propranolol alone.

Please see the following page for the complete prescribing information.

SEARLE

5-MG/24-HR; 10-MG/24-HR

NITRODISC™

(nitroglycerin)

DESCRIPTION: The Nitrodisc pad incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths that release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface (see HOW SUPPLIED section).

ACTIONS: When a Nitrodisc pad is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart and peripheral vasculature) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is due to a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In addition, a direct effect of nitroglycerin on the coronary vessels is recognized as well.

In clinical studies, transdermal absorption of nitroglycerin from Nitrodisc occurred in a continuous and well-controlled manner for a minimum of 24 hours. Therapeutic plasma levels were attained within 1 hour after the application of the pad and remained in the therapeutic range for 24 hours. Plasma levels of nitroglycerin were still detectable 30 minutes after removal of the system.

The amount of nitroglycerin released (5 mg/24 hr or 10 mg/24 hr) represents the mean absorption rates through skin determined during clinical evaluations. Absorption may vary among individuals.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: A Nitrodisc pad should be applied once each day. To use the pad, follow the instructions on the package. Nitrodisc should be applied to a skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new pad should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller pad, and that the larger pad be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

PATIENT INSTRUCTIONS FOR APPLICATION: These are provided with the product.

HOW SUPPLIED:

Nitrodisc	5 mg/24 hr	10 mg/24 hr
Drug released per 24 hours	5 mg	10 mg
Total drug content	16 mg	32 mg
Drug releasing surface	8 cm^2	16 cm^2

Nitrodisc pads are supplied in cartons of 30. Store at a controlled room temperature of 59°-86°F (15°-30°C). **Do not refrigerate.** Extremes of temperature and humidity should be avoided.

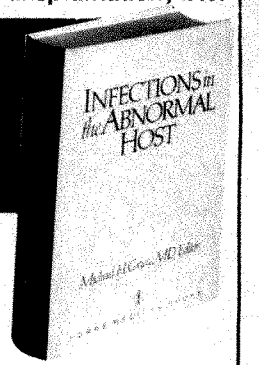
INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

Ibuprofen-Mediated Infarct Size Reduction: Effects on Regional Myocardial Function in Canine Myocardial Infarction

PHILIP C. KIRLIN, MD,* JOSEPH L. ROMSON, PhD,† BERTRAM PITT, MD, GERALD D. ABRAMS, MD, M. ANTHONY SCHORK, PhD, and BENEDICT R. LUCCHESI, PhD, MD

Normal, marginal, and central ischemic regional myocardial function were evaluated in a canine model of myocardial infarction during 90 minute left circumflex coronary artery occlusion in 25 anesthetized dogs randomly assigned to intravenous ibuprofen infusion (n = 13, 5.36 mg/kg/h beginning 1 hour before occlusion) or vehicle solution as control (n = 12) and in 15 conscious, unsedated dogs 48 and 72 hours after 90 minute circumflex artery occlusion followed by reperfusion (ibuprofen, 5.36 mg/kg/h by intravenous infusion over 7 hours beginning 1 hour before occlusion, n = 7; or vehicle solution infusion as control, n = 8).

Miniature subendocardial sonomicrometer crystal pairs were used to calculate left ventricular regional end-diastolic segment length, end-systolic segment length, and regional percent systolic shortening. Infarct size was estimated in 72 hour animals by a postmortem dual perfusion technique using triphenyltetrazolium histochemical dye and Evan's blue dye for determination of infarct area, risk area, and area not at risk. Ibuprofen treatment significantly reduced infarct size expressed as percent of risk area (mean ± standard deviation of 44.6 ± 18 versus 64.4 ± 16% for control dogs, $p < 0.05$) but it did not improve normal, marginal, or ischemic region end-diastolic length, end-systolic length or percent systolic shortening during coronary occlusion in anesthetized dogs or after reperfusion in conscious animals at 48 and 72 hours, and it did not enhance inotropic reserve at 72 hours in conscious animals. During 90 minute circumflex occlusion in anesthetized dogs, ibuprofen was associated with increases in systemic arterial pressure and worsened ischemic regional percent systolic shortening.

Thus, ibuprofen does not improve normal, marginal, or ischemic zone regional myocardial function during acute ischemia or 48 or 72 hours after myocardial reperfusion despite a significant reduction of infarct size.

Reducing the extent of ischemic injury has been proposed as a rational goal in the management of acute myocardial infarction.[1] Initial attempts to achieve this goal centered primarily on hemodynamic interventions which lessened myocardial oxygen consumption or improved blood flow or oxygen delivery to ischemic myocardium; more recent investigations have evaluated a variety of agents whose primary effect is not hemodynamic but rather anti-inflammatory. The hypothesis supporting the use of these agents is that a significant determinant of ultimate ischemic injury is the inflammatory process itself. Among the many agents currently under evaluation is ibuprofen, a nonsteroidal antiinflammatory agent clinically employed for rheumatic disease.[2] Experimental studies have demonstrated a myocardial protective effect of ibuprofen in a variety of animal models,[3–7] presumably attributable to its antiinflammatory actions which affect arachidonic acid metabolism and consequent physiologic events.[8]

However, few studies on myocardial infarct size reduction involving either hemodynamic or antiinflammatory interventions have addressed the issue of the functional integrity of the salvaged myocardium or the effect of these agents on the function of myocardium removed from the area of ischemic injury. In order to assess the myocardial protective effect of ibuprofen on regional myocardial function, the following investigation was undertaken using implantable subendocardial

sonomicrometer crystals to measure segment length changes in normal, marginal and ischemic regions[9] in a canine model of left circumflex coronary artery occlusion and reperfusion. In this study, regional myocardial function was evaluated in open-chest, anesthetized dogs during coronary artery occlusion and in conscious, unsedated dogs 48 and 72 hours after circumflex occlusion and subsequent myocardial reperfusion.

Methods

Regional Myocardial Function During Coronary Artery Occlusion

Coronary occlusion: In order to assess the acute effects of ibuprofen on regional function during evolving myocardial injury due to coronary artery occlusion, 25 dogs were studied in the open-chest anesthetized state. Healthy male mongrel dogs weighing 10.2 to 18.9 kg (mean ± standard deviation 13.9 ± 1.9) were anesthetized with 30 mg/kg intravenous sodium pentobarbital and mechanically ventilated on room air by a Harvard animal respirator (Harvard Apparatus, Millis, Massachusetts) using an endotracheal tube. A left 5th intercostal space thorocotomy was performed and the pericardium incised and sutured to form a pericardial cradle. The left circumflex coronary artery was isolated distal to the left atrial appendage proximal to major branches. A zone of cyanosis was determined to be at least 9 cm^2 during transient (10 to 15 second) coronary occlusion. Three pairs of commercially manufactured miniature (3 mm) piezoelectric crystals (800 kHz frequency in radial mode with a resolution capability of 0.1 to 0.5 mm) connected to an oscilloscope sonomicrometer (Norland Instruments sonomicrometer crystals and NI-202 sonomicrometer) were implanted 1 to 2 cm apart in the left ventricular subendocardium (Fig. 1). One crystal pair (central ischemic zone) was implanted in the posterolateral left ventricular surface in the center of the cyanotic zone as determined by the transient circumflex occlusion, and a 2nd pair (marginal area) was implanted in the anterolateral left ventricular wall to straddle the border between cyanotic and noncyanotic zones. The marginal area was defined in the present study as a region of intermediate function between normal and ischemic zones.[9] Normal zone sonomicrometer crystals were implanted on the anterior left ventricular wall in the region supplied by the left anterior descending coronary artery well removed from the ischemic area as determined by the zone of cyanosis. The crystals were implanted in a plane perpendicular to the base-apex cardiac axis and secured by an epicardial suture around the connecting wires as they emerged from the myocardium. Repeated calibrations at 1 μs intervals were obtained to eliminate variation due to signal drift.

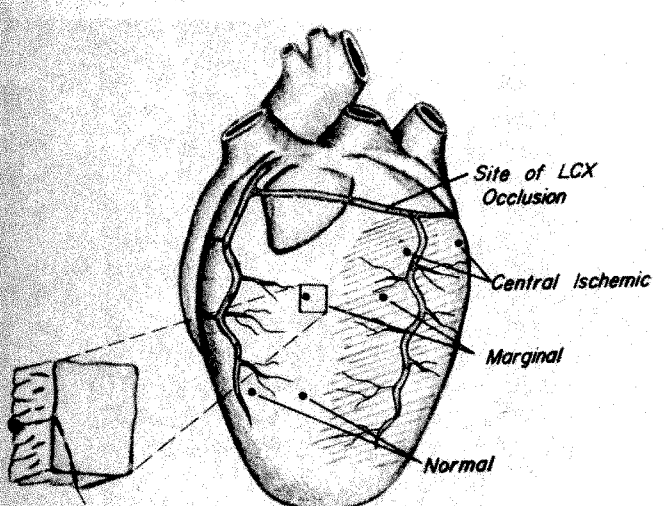

FIGURE 1. Diagram of subendocardial sonomicrometer crystal placement in normal, marginal, and central ischemic left ventricular regions. LCX = left circumflex coronary artery. See text for discussion.

In addition, a small left neck incision was made for insertion of a polyethylene carotid artery catheter for blood pressure measurement and an external jugular catheter for infusion of ibuprofen or control solution. The carotid artery catheter was connected to a Statham P23DC pressure transducer. Mean arterial pressure was calculated as diastolic pressure plus one third of the pulse pressure.

Ibuprofen infusion: Crystalline ibuprofen (sodium salt) was dissolved in 0.2 *M* sodium carbonate and adjusted to a pH of 8 by 1.0 N HCl. Solutions were mixed fresh before each experiment and diluted to 50 ml in physiologic saline solution. The ibuprofen dose employed was 5.36 mg/kg/h (7.14 ml/h of ibuprofen solution) by continuous intravenous infusion beginning 1 hour before occlusion and continuing throughout occlusion (90 minutes). This dose is similar to that used in a previous investigation[6] with the exception of initiation of the infusion before occlusion in the present study. Vehicle solution prepared in an identical manner without ibuprofen served as a control. A Harvard infusion pump was used to provide a constant infusion rate. Animals were randomly assigned to their treatment groups (13 ibuprofen, 12 control). A lead II electrocardiogram was monitored throughout the experiment.

After instrumentation, visible epicardial arterial anastomoses between the left anterior descending and circumflex coronary arteries were ligated to eliminate potentially large collateral routes of blood flow.[10] A subtotal left circumflex coronary artery stenosis was produced just distal to the left atrial appendage by tying 1-0 silk suture around both the artery and an 18 gauge needle followed by immediate needle removal; subsequent total circumflex artery occlusion was performed after 10 minutes with a total duration of occlusion of 90 minutes. Three mg/kg of intravenous lidocaine and 3 mg/kg of intramuscular lidocaine were administered at the time of coronary artery occlusion as antiarrhythmic therapy.[11] Approximately one fourth of the animals developed ventricular fibrillation during coronary occlusion, which was readily converted to sinus rhythm within 30 to 60 seconds by low energy (10 to 20 J) direct current cardioversion using epicardial paddles. No myocardial dysfunction has been reported at these energy levels.[12]

Regional myocardial segment length: Measurement of regional myocardial segment length was obtained by converting sonomicrometer crystal transit time in microseconds to distance in millimeters using a known value for the velocity of ultrasound in myocardium at the frequency employed: Distance (mm) = transit time (μs) × ultrasound velocity in myocardium (1.58 mm/μs).[13] Before occlusion, end-diastolic length was defined in each segment as the maximal crystal separation in millimeters before the onset of the carotid artery systolic pressure rise, and end-systolic length was defined as the minimal crystal separation in millimeters before the dicrotic notch of the carotid artery pressure tracing. Nonsimultaneous end-diastolic or end-systolic timing in marginal or

ischemic segments in relation to normal segments was noted before occlusion and used as a reference to determine end-diastole and end-systole in the presence of dyskinesia during coronary artery occlusion. Measurement of absolute end-diastolic and end-systolic length in millimeters were obtained and regional percent systolic shortening defined as end-diastolic minus end-systolic length divided by end-diastolic length ×100%. Subendocardial crystal placement was confirmed by postmortem examination.

A Grass model 7 polygraph was used to record measurements at a paper speed of 100 mm/s. Determination of carotid artery pressure, heart rate, and regional segment lengths and percent systolic shortening were obtained before and at the end of 90 minutes of coronary occlusion. All measurements were obtained at end-expiration and when the animal was free of arrhythmias.

Regional Myocardial Function 48 and 72 Hours After Coronary Artery Occlusion-Reperfusion

The effect of ibuprofen on regional myocardial function and infarct size was evaluated in conscious, unsedated dogs after left circumflex coronary artery occlusion with subsequent myocardial reperfusion in the anesthetized state. Fifteen healthy male mongrel dogs weighing 13.6 ± 1.5 kg (range 10.2 to 15.8) were used. Instrumentation, baseline regional function measurements, and 90 minute circumflex occlusion followed by reperfusion were performed using aseptic technique in pentobarbital anesthetized, open-chest dogs as in the acute occlusion study. Animals were randomly assigned to either ibuprofen (n = 7) or vehicle as control (n = 8). Solutions were prepared as before and administered intravenously by Harvard infusion pump over 7 hours beginning 1 hour before occlusion with an ibuprofen dose of 5.36 mg/kg/h (7.14 ml/h of ibuprofen solution) or with an identical volume of vehicle as a control. Ischemic zone sonomicrometer crystals were associated with greater postoperative mortality in preliminary studies and therefore implanted in only 4 animals in each group. As in the acute occlusion study, a critical circumflex stenosis was placed 10 minutes before total occlusion using an 18 gauge needle and 1-0 silk suture. A Carolina Medical Electronics electromagnetic flow probe was placed around the circumflex artery proximal to the subtotal occlusion to document a critical stenosis (defined as a stenosis causing at least a 50% reduction in peak reactive hyperemic flow after 10 seconds of coronary occlusion without altering basal flow or sonomicrometer crystal segment length). This subtotal critical stenosis was left in place throughout the remainder of the experiment (until the animals were killed at 72 hours).

Coronary occlusion and reperfusion: Total left circumflex occlusion was performed using soft plastic tape for 90 minutes and the occlusion was slowly released over 5 to 10 minutes. Intravenous lidocaine, 3 mg/kg, was administered on reperfusion. Reperfusion occurred in all animals as documented by 3 or more of the following criteria: (1) the onset of ventricular arrhythmias within 15 to 30 minutes of occlusion release; (2) a decrease in marginal and ischemic region end-diastolic and end-systolic segment length on release of the occlusion; (3) at least 5 ml/min of circumflex artery flow on occlusion release documented by electromagnetic flow probe; and (4) the absence of visible coronary artery thrombosis at 72 hours when the animal was killed.

After reperfusion, the chest was closed and the animals were allowed to recover. Intramuscular ampicillin, 6 mg/kg, was administered twice on the day of surgery and daily thereafter. No recordings were obtained until 48 hours after surgery because of frequent ventricular arrhythmias. At 48 and 72 hours, recordings of sonomicrometer crystal segment lengths were obtained in the conscious, unsedated state with the animal standing upright in a nylon sling. In order to assess residual ventricular contractile function, inotropic reserve was also tested at 72 hours after coronary occlusion-reperfusion, 5 minutes after administration of the beta-adrenergic stimulant prenalterol (30 μg/kg intravenous bolus).[14]

Determination of infarct size and risk area: Animals were then reanesthetized with sodium pentobarbital, the chest was reopened, and the hearts were electrically fibrillated and rapidly excised for immediate postmortem in vitro determinations of infarct size and risk area by a dual perfusion technique using 4% triphenyltetrazolium chloride mixed with phosphate buffer for histochemical staining of dehydrogenase enzyme and 0.5% Evan's blue flow-dependent staining as described in detail elsewhere.[7,15] Briefly, this method involves simultaneous selective left circumflex perfusion with triphenyltetrazolium and nonselective retrograde aortic perfusion with Evan's blue dye at physiologic pressure (100 mg Hg), with the resultant Evan's blue staining tissue identifying the area not at risk of ischemic injury and the remaining tissue representing the area at risk with red triphenyltetrazolium staining tissue identifying the viable, noninfarcted region, and the remaining tissue (unstained) representing the area of infarction. After staining, the heart was sliced from apex to base in 5 mm thick transverse sections and the atria and right ventricle were excised. Left ventricular weight was recorded and left ventricular slices were traced on transparent plastic sheets for hand planimeter determination of left ventricular area, area at risk, and area of infarction. Infarct size was measured as percent of area at risk and percent of total left ventricular area. The anatomic perfusion bed of an occluded coronary has been shown to correlate well with the area at risk of infarction in experimental canine coronary artery occlusion.[10] Subendocardial crystal placement was also confirmed at postmortem evaluation.

Light microscopic evaluation of hematoxylin and eosin stained left ventricular slices was performed in a blinded manner on 72 hour specimens from all animals in each group to assess the morphologic integrity of myocardial cells and the inflammatory response.

Statistical methods: All results are expressed as mean ± 1 standard deviation. Statistical analysis was performed by a computerized statistical program of the University of Michigan Statistical Research Laboratory (Michigan Interactive Data Analysis System). Two factor analysis of variance for repeated measures (profile analysis)[16] was employed for the same variable measured more than twice, and paired or unpaired *t* test was performed as appropriate on data measured only twice. A probability value (p) less than 0.05 was considered significant.

Results

Regional myocardial function during coronary artery occlusion: In anesthetized, open-chest dogs 90 minute circumflex coronary artery occlusion resulted in a marked alteration of contractile function manifested by greatly diminished marginal and ischemic segment systolic shortening and increased end-diastolic and end-systolic segment lengths in all 3 regions, indicative of ischemia-associated ventricular dilation[9] (Fig. 2, Table I). Ibuprofen administration did not decrease these segment length increases or improve systolic shortening in any region during coronary artery occlusion. In the central ischemic zone, ibuprofen-treated animals developed more severe impairment of

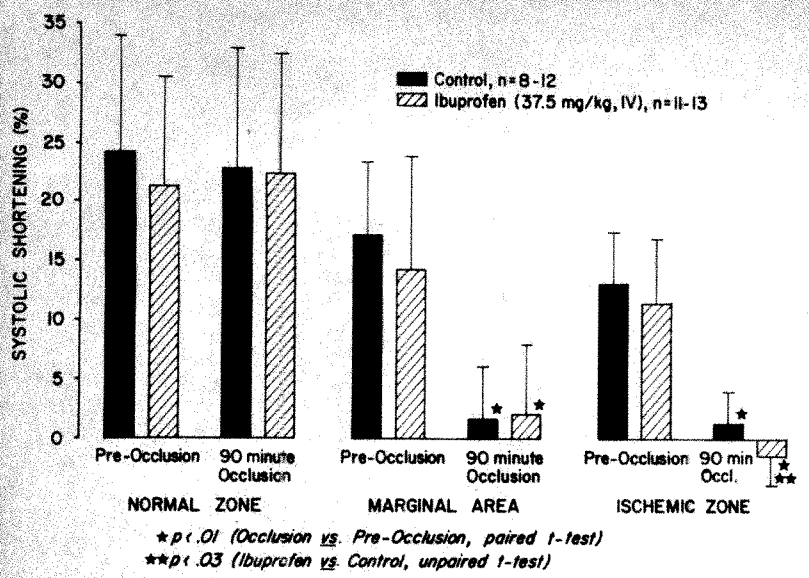

FIGURE 2. Effect of ibuprofen on regional myocardial function after 90 minute left circumflex coronary artery occlusion. Marginal and ischemic zone percent systolic shortening was reduced in both groups compared with preocclusion (paired *t* test), and ibuprofen animals had significantly worse systolic shortening than controls in the ischemic zone at the end of the 90 minute occlusion (unpaired *t* test).

systolic shortening with paradoxic systolic expansion (dyskinesia). Heart rate was not altered by ibuprofen during coronary occlusion; however, mean carotid artery pressure rose significantly with a rise in pressure-rate product (the product of mean arterial pressure and heart rate divided by 100) (Table I).

Regional myocardial function 48 and 72 hours after coronary artery occlusion-reperfusion: Serial changes in regional myocardial function in a control animal before, during, and up to 72 hours after coronary artery occlusion-reperfusion are shown in Figure 3. Similar baseline regional myocardial function was present in ibuprofen-treated and control animals in the anesthetized, open-chest state before coronary occlusion (Table II, Fig. 4 to 6). In the conscious, unsedated state 48 and 72 hours after occlusion with myocardial reperfusion, both marginal and ischemic zone systolic shortening were impaired despite partial recovery, while normal zone systolic function remained relatively unaltered. Ibuprofen treatment did not improve systolic function or decrease ventricular end-diastolic or end-systolic segment lengths in normal, marginal, or ischemic regions at 48 hours or 72 hours before or after inotropic stimulation.

A significant reduction in the extent of ischemic injury as measured by percent of the area at risk infarcted was noted in ibuprofen-treated animals (44.6 ± 18%) compared with control animals (64.4 ± 16%, p

Values are mean ± 1 standard deviation. Differences between ibuprofen and control groups were not significant (analysis of variance for repeated measures).

<0.05, unpaired t test) despite a similar area at risk and left ventricular weight (Fig. 7). The percent of total left ventricle infarcted was substantially reduced by ibuprofen (19.7 ± 9.1% versus 26.0 ± 5.5% for controls), but this did not reach significance ($p = 0.12$, unpaired t test). By visual inspection of stained ventricular slices, the predominant area of tissue salvage in ibuprofen-treated animals was at the epicardial and lateral margins of the infarct.

Light microscopic analysis of hematoxylin and eosin stained left ventricular slices revealed no evident differences in the extent of inflammatory infiltrate or hemorrhage or in the appearance of necrotic myocardial cells. The appearance of contraction band lesions and of fibroblastic proliferation was comparable in both groups.

Visual inspection of the left circumflex coronary artery after death demonstrated no detectable thrombus in ibuprofen-treated animals and visible thrombus in 1 of 8 control animals.

Discussion

Rationale for this model: Coronary artery occlusion with myocardial reperfusion through a critical stenosis as employed in this model may more closely simulate the evolution of human myocardial infarction than permanent coronary artery occlusion. DeWood et al.[17] demonstrated a progressive decline in the prevalence of total coronary occlusion over 24 hours in patients with acute myocardial infarction, a finding consistent with coronary artery spasm superimposed on fixed obstructive disease[18] or with partial resolution of a coronary artery thrombosis,[17] or both. In addition, experimental animal data indicate that reperfusion may enhance survival[19] and improve the likelihood of myocardial functional recovery.[20] Thus, a rationale exists for the coronary artery occlusion-reperfusion model of myocardial infarction.

Possible mechanisms of ibuprofen's myocardial protective effect: The present study demonstrates a myocardial protective effect of ibuprofen during experimental myocardial infarction without improvement of normal, marginal, or ischemic regional myocardial function during coronary artery occlusion or 48 or 72 hours after reperfusion or of inotropic reserve at 72 hours. The reduction in infarct size noted with ibuprofen in this study is consistent with previous investigations[3–7] employing a variety of dosage schedules and routes of administration. While the mechanisms of infarct size reduction mediated by ibuprofen have not been established, several possibilities have been evaluated.

First, it is unlikely that ibuprofen exerts a hemodynamic effect through diminished myocardial oxygen consumption or increased myocardial blood flow. Jugdutt et al.[6] and Romson et al.[7] noted no significant effect of ibuprofen on blood pressure or heart rate during myocardial ischemia, and the drug has only a minimal effect on ventricular contractile force.[4] In our present study, continuous ibuprofen infusion beginning 1 hour before ischemia resulted in significant elevations of systemic arterial pressure (Table I) without an effect

on heart rate after 90 minutes of coronary occlusion. This result, not found in previous investigations employing different models of ischemia and different drug administration schedules, would increase rather than decrease myocardial oxygen consumption and thus tend to worsen ischemic injury.[21] In addition, directly measured myocardial oxygen consumption is not altered by ibuprofen administration during 60 minutes of normothermic global ischemia in the isolated, blood-perfused feline heart.[15]

Increased blood flow to ischemic tissue by direct coronary artery vasodilation or enhanced collateral blood flow is also an unlikely mechanism of ibuprofen's beneficial effect. Tracer microsphere studies in experimental myocardial infarction have failed to demonstrate increased blood flow to ischemic tissue up to 6 hours[6] or 24 hours[15] after coronary occlusion in ibuprofen-treated experimental animals.

An antithrombotic effect of ibuprofen is a 2nd possible mechanism by which ibuprofen may reduce infarct size.[7] In the present study, however, coronary artery reperfusion occurred in all animals and only 1 of 8 control animals developed visible thrombus at 72 hour postmortem examination. Also, the antithrombotic agent sulfinpyrazone does not appear to reduce infarct size.[22] Thus, it is improbable that an antithrombotic effect of ibuprofen played a role in the present study. The potentially related phenomenon of platelet deposition at the site of ischemic injury also occurs in myocardial infarction and is diminished by aspirin.[23] Ibuprofen, however, does not alter indium-111–labeled platelet accumulation in the ischemic myocardium.[24]

A 3rd possible mechanism by which ibuprofen may exert a myocardial protective effect is its antiinflammatory action, related to inhibition of the arachidonic acid pathway.[8] Cyclooxygenase enzyme inhibition could have a beneficial effect in ischemic tissue through a reduction in the synthesis of thromboxane, a potent vasoconstrictor. However, other nonsteroidal cyclooxygenase inhibitors do not reduce the extent of experimental ischemic injury.[22,25,26] An alternative hypothesis also related to the arachidonic acid cascade which may in part explain ibuprofen's beneficial effect in myocardial ischemia is inhibition of the lipoxygenase pathway. This branch of the arachidonic acid cascade is capable of producing powerful chemotactic substances (hydroxyeicosatetraenoic acid [HETE] derivatives)[27] and leukotrienes, which are additional mediators of the inflammatory response.[27] Ibuprofen has been shown to inhibit the synthesis of 12-HETE, catalyzed by a putative peroxidase enzyme.[28] Lipoxygenase pathway inhibition may in part account for ibuprofen's ability to inhibit the migration of polymorphonuclear leukocytes,[29] an effect noted with ibuprofen in experimental myocardial ischemia.[24]

A 4th mechanism of potential significance in explaining ibuprofen's myocardial protective action is inflammatory cell lysosomal membrane stabilization, an effect suggested by data from noncardiac in vitro preparations[30–32] and by indirect evidence in canine cardiac ischemia.[4] In addition, ibuprofen affects kinin and histamine release[2] and superoxide radical formation,[33,34] which may in part account for its anti-inflammatory effect.

The use of lidocaine in our study could also reduce the severity of myocardial ischemic injury.[35] Our data, however, indicate extensive infarction despite lidocaine administration and an additional beneficial effect of ibuprofen if lidocaine myocardial preservation occurred.

Discordance between infarct size reduction and functional recovery: The discrepancy between myocardial infarct size and functional recovery in this investigation may be due to several factors. Improvement in regional myocardial function may occur at a time not evaluated in this study. A functionally beneficial effect of ibuprofen between the onset of reperfusion and 48 hours cannot be excluded; in the present study a functional assessment was not performed during that time because of marked beat-to-beat segment length changes associated with frequent reperfusion arrhythmias. Alternatively, improvement in myocardial function with ibuprofen could occur at a time later than 72 hours. This possibility is supported by sonomicrometer crystal data in conscious dogs studied up to 4 weeks after 2 hour coronary artery occlusion.[20] Substantial recovery of marginal and ischemic segment systolic shortening occurred 1 to 4 weeks after coronary artery occlusion-reperfusion. Further studies will be necessary to determine whether ibuprofen treatment alters regional myocardial function more than 3 days after myocardial infarction.

Improvement in indexes of myocardial function other than subendocardial segment length changes is another possible explanation of the discordance between infarct size reduction and functional recovery in this investigation. Roan et al.[36] noted spontaneous improvement in ischemic zone ventricular wall paradoxic systolic thinning between 24 hours and 1 week after coronary artery occlusion. Other measures of regional function which were not evaluated in this study include mid-myocardial and subepicardial segment length changes, which may have been altered more than subendocardial functional measurements in view of predominant subepicardial tissue salvage by gross inspection.

A persistent inability of ibuprofen to significantly improve marginal or ischemic region myocardial function despite infarct size reduction as determined by histochemical staining is also possible. Glucocorticoids have been implicated in "mummification" of ischemic myocardium (loss of nuclei with intact myofibril striations and sarcolemma).[37] Such tissue may retain the ability to stain dehydrogenase with triphenyltetrazolium despite the loss of functional integrity. The absence of such a "mummification" effect on light microscopic evaluation in this investigation provides evidence against that possibility.

A recent publication by Kloner et al.[38] demonstrated that a 15 minute period of coronary occlusion followed by reperfusion, which is not associated with the development of necrosis, nonetheless results in prolonged biochemical, functional, and ultrastructural abnormalities. Wall motion, as determined by ultrasonic

crystal measurements, was still reduced at 3 days of reperfusion, whereas creatine phosphate levels and regional myocardial blood flow recovered rapidly and had returned to normal after 90 minutes of coronary reperfusion. Brief periods (15 minutes) of regional ischemia followed by full reperfusion, therefore, can be associated with abnormalities in cardiac contractile function which persist for a relatively long period. Bush et al.[39] showed that the biochemical abnormalities associated with regional ischemia after reperfusion also extend to the normally perfused myocardium. Thus, a regional ischemic event may produce an influence on a remote region of myocardium which may persist for several days after the restoration of coronary blood flow.[38,39]

In the present investigation, coronary artery occlusion was maintained for 90 minutes and was followed by reperfusion in the presence of a critical stenosis. It is conceivable that the failure of the salvaged myocardial segment to regain contractile function could be related to the relatively persistent derangement in segment length shortening which is seen even in the absence of cellular necrosis. Future attempts to assess the potential benefits of pharmacologic interventions in protecting ischemic myocardium should consider the functional recovery of the "salvaged" myocardium days to weeks after the ischemic episode.

Implications: Intravenous ibuprofen infusion reduces myocardial infarct size without improving normal, marginal, or ischemic region myocardial function during coronary artery occlusion or 48 or 72 hours after myocardial reperfusion, or inotropic reserve at 72 hours. Further studies are necessary to assess ibuprofen's effect on regional myocardial function at intervals greater than 72 hours after myocardial infarction and to further elucidate the mechanisms by which ibuprofen exerts a protective effect on ischemic myocardial tissue.

Acknowledgment

We acknowledge the assistance of James Kipnis in performing surgical procedures and Dixie Thomas for the preparation of this manuscript. Upjohn Laboratories, Kalamazoo, Michigan, kindly provided ibuprofen.

Protective Effects on Isolated Hearts With Developing Infarction: Slow Channel Blockade by Diltiazem Versus Beta-Adrenoceptor Antagonism by Metoprolol

CHRISTIAN W. HAMM, MD, FRANCIS T. THANDROYEN, MRCP, and LIONEL H. OPIE, MD

Slow channel inhibitors (calcium antagonists) and beta-adrenoceptor antagonists may theoretically protect the infarcting myocardium by different mechanisms. Thus, beta-receptor antagonism reduces the oxygen demand by the combined effects of bradycardia, decreased arterial pressure, and reduced contractility, whereas slow channel inhibition chiefly increases coronary blood flow and decreases the afterload by peripheral vasodilation. The present study was designed to assess and compare the effects of the beta-receptor antagonist metoprolol with those of the calcium channel inhibitor diltiazem on cellular damage and mechanical function in the isolated working rat heart subject to coronary artery ligation. We compared the highest concentrations of both agents that could be tolerated in this preparation: diltiazem 4×10^{-7} *M* and metoprolol 10^{-4} *M*. These concentrations were equally effective in reducing enzyme release, which was taken as an index of cellular damage, and in preserving high energy phosphate contents in the infarcting myocardium. However, the 2 agents exhibited opposite effects on coronary flow rates and mechanical function. Compared with diltiazem metoprolol reduced total coronary flow, cardiac output, and left ventricular work and efficiency immediately after coronary artery ligation. However, diltiazem even favorably influenced the mechanical performance of the isolated heart compared with that of untreated control hearts during the 60 minutes of regional myocardial ischemia. These benefits were similarly apparent when the hearts were paced to the rate of control hearts. The presumed mechanism was coronary vasodilation, because afterload increased as left ventricular power production increased in this model.

These results suggest that slow channel inhibition by diltiazem has advantages over beta-receptor antagonism by metoprolol in protecting the infarcting myocardium and that further evaluation of diltiazem in other preparations is warranted.

Modification of infarct size is currently an area of great endeavor in cardiac research.[1] Many pharmacologic and metabolic principles have been studied in the experimental animal with the aim of limiting the extent of cell necrosis caused by acute myocardial ischemia. One concept follows the hypothesis of Maroko et al.[1] that the extent of ischemic injury is related to the myocardial oxygen balance. On this basis, several studies were undertaken with beta-adrenoceptor antagonists and, more recently, slow channel inhibitors (calcium antagonists). Although both types of intervention could act directly on the heart to diminish oxygen requirements by reducing left ventricular contractile force and heart rate,[2–4] in practice the depressive effect of calcium antagonists is thought to be modified by afterload reduction with a reflex increase in sympathetic tone, so that the sinus rate rarely decreases.[5] Furthermore, calcium antagonists can exert specific therapeutic effects in concentrations that do not cause myocardial depression.[6] An additional effect of slow channel inhibitors is to further reduce oxygen demand and to increase oxygen supply to the ischemic myocardium by their peripheral and coronary artery vasodilating activity, which could result in reduced left ventricular afterload and

improved myocardial collateral flow, respectively.[2] In contrast, there is some concern that beta-adrenoceptor antagonists, particularly noncardioselective compounds, might be associated with vasoconstrictive properties.[7]

Favorable results with experimental myocardial ischemia were reported for both beta-antagonists and calcium channel inhibitors[8–16] and extensive clinical trials are already projected. However, there is as yet no study that compares these two interventions directly under the same experimental condition. Therefore, the present investigation was designed to assess and compare the effects of beta-adrenoceptor antagonism and slow channel blockade on cellular damage and mechanical function during acute regional myocardial ischemia. For our study we chose the cardioselective beta-adrenoceptor antagonist metoprolol, reasoning that cardioselectivity should diminish the tendency of beta-antagonists to cause coronary vasoconstriction,[7] and compared it with the recently introduced slow channel inhibitor diltiazem.[12]

Methods

Perfusion model: Male Long-Evans rats (270 to 330 g) were anesthetized with ether and given 200 IU of heparin intravenously. The heart, weighing about 1 g (0.959 to 1.126 g, no significant differences between all groups), was rapidly excised and arrested in chilled perfusion fluid. After 15 minutes of retrograde preperfusion through the aorta, the working heart technique described by Neely et al.[17] was started. In this model the isolated heart is filled by the left atrium at a constant filling pressure of 10 cm H_2O and pumps spontaneously against a hydrostatic pressure load of 100 cm of water. Part of the fluid ejected from the left ventricle supplies the coronary arteries, drains into the right heart, and is collected from the pulmonary arteries as coronary flow. Aortic output at the top of the hydrostatic pressure column and coronary flow were measured by calibrated cylinders and added together for cardiac output. The perfusate used in this recirculating system was a Krebs-Henseleit bicarbonate buffer, maintained at 37°C and aerated with 95% O_2 and 5% CO_2, and contained 11 m*M* of glucose as substrate. The oxygen uptake was determined from samples taken simultaneously from the left atrial cannula and directly from the pulmonary artery measured as the oxygen tension (Radiometer, Copenhagen) and related to the coronary flow rate.[17]

Acute regional myocardial ischemia was produced as described by Kannengiesser et al.[18] The left main coronary artery was ligated with 6-0 silk by a 3/8 circle taper point needle (K-801 H, Ethicon). The stitch was placed with a small width about 2 mm below the aortic root. The coronary artery was ligated after 20 minutes of left atrial perfusion and the heart was perfused an additional 60 minutes. Pharmacologically active agents were added to the perfusate 10 minutes before ligation. Measurements of coronary flow, cardiac output, peak aortic pressure, myocardial oxygen uptake, and release of lactate dehydrogenase were taken 10 minutes before and at the time of coronary artery ligation as well as 10, 20, 40, and 60 minutes thereafter.

Enzyme release: The release of lactate dehydrogenase is a sensitive marker of myocardial cell viability loss,[19] and the pattern of release from the isolated heart is similar to that of creatine kinase.[20] We measured the arteriovenous difference[20] of lactate dehydrogenase activity at the aforementioned time intervals with a Gilford 300-V spectrophotometer, using conventional assay techniques. The cumulative rate of enzyme loss was calculated, assuming linear functions, and expressed in international units per gram wet weight of heart.

Hemodynamic measurements: Aortic pressure was measured by a Statham P23 Db pressure transducer and monitored on a Devices 2 channel M2 direct writer pen recorder. Total power production (work) of the heart was calculated as the sum of pressure and kinetic power[21] according to the formulas:

$$\text{Pressure power} = p = 0.002222 \times P_s \times CO$$

$$\text{Kinetic power} = k = 1/(432 \times 10^7) \times [d(CO)^3]/A^2 \times (T/Te)^2$$

where P_s = peak systolic pressure (mm Hg), CO = cardiac output (ml/min), d = density of perfusage (1 g/cm^3), A = internal cross-sectional area of the aortic cannula (cm^3), T = cycle time (ms), and Te = ejection time (ms). The results are expressed in millijoules per second per gram heart weight. The efficiency of mechanical power production was calculated as total power divided by oxygen uptake (J/ml O_2).

Pharmacologically active agents: The beta-adrenoceptor antagonist metoprolol (Lopressor®, Geigy)[22] was used in a concentration of 1×10^{-4} *M*. The slow channel inhibitor diltiazem (Herbesser®, Tanabe Seiyaku)[23] was used in a concentration of 4×10^{-7} *M*, which was the highest dose that did not cause complete heart block. The aforementioned concentrations chosen for each compound gave best protection against cellular damage in dose-response curves.[24,25]

Because both drugs significantly reduced the heart rate, a series of 6 hearts each was paced by the right atrium at the heart rate of control hearts (230 beats/min) in order to exclude heart rate effects on enzyme release and mechanical performance. Pacing was started immediately after administration of the drugs as soon as the heart rate dropped below 230 beats/min.

Biochemical studies: To distinguish infarcting from noninfarcting myocardium, disulfine blue dye was injected into the left atrium just prior to freeze-clamping of unpaced hearts with Wollenberger tongs, precooled to the temperature of liquid nitrogen. Samples of the midischemic and uninvolved tissue of approximately 100 mg each were analyzed for adenosine triphosphate and phosphocreatine as previously described.[26] If clear separation of stained and unstained tissue was not possible because of the timing or the angle of clamping, the hearts were discarded for biochemical analysis.

Statistical procedures: Results were expressed as means ± standard error of the mean. P values were calculated by the appropriate Student's *t* test and $p < 0.05$ was taken as significant, using 2-tailed values and corrections for unequal variances. If multiple comparisons were performed, Bonferroni's correction was applied and the level of significance was raised accordingly.

Results

Effects of Metoprolol and Diltiazem on the Working Rat Heart Before Coronary Artery Ligation

The administration of metoprolol and diltiazem reduced the heart rate of the working heart from 244 ± 8 to 168 ± 14 beats/min ($p < 0.001$) and from 256 ± 10 to 212 ± 9 beats/min ($p < 0.05$), respectively. Diltiazem produced no change in cardiac output (56.2 ± 1.2 versus 54.0 ± 1.2 ml/min after diltiazem), whereas with metoprolol the cardiac output decreased from 58.1 ± 2.0

Values are mean ± standard error of the mean for number of hearts in brackets.

ml/min to 48.7 ± 1.7 ml/min ($p < 0.001$). This decrease apparently was the result of a reduced heart rate because it was abolished by supraventricular pacing (55.8 ± 2.7 versus 52.7 ± 3.8 ml/min after metoprolol) at a rate of 230 beats per min, which was the heart rate of untreated control hearts after coronary artery ligation.

Diltiazem increased the coronary flow from 14.2 ± 0.6 to 15.8 ± 0.6 ml/min ($p < 0.001$). In contrast to diltiazem and possibly as an effect of reduced oxygen requirements, metoprolol decreased the coronary flow from 13.2 ± 0.4 to 11.8 ± 0.3 ml/min ($p < 0.005$). Similar results for coronary flow rates, oxygen uptake, and left ventricular work and efficiency were obtained in the paced groups. However, during the elevated heart rate an increase in oxygen uptake from 159 ± 5 to 187 ± 8 μl/min/g ($p < 0.01$) was followed by a reduction in efficiency from 5.52 ± 0.17 to 4.33 ± 0.17 J/ml O_2 ($p < 0.005$) in the diltiazem group. It may be speculated that this effect was the result of an intrinsic limitation of this isolated model for further vasodilation, because the coronary flow accounts for about one third of the cardiac output ejected from the left ventricle.

Effects of Metoprolol and Diltiazem on the Rat Heart After Coronary Artery Ligation

Coronary flow (Table I): Ligation of the left main coronary artery reduced the total coronary flow rate in untreated control hearts by 49% from 15.0 ± 0.6 to 7.6 ± 0.2 ml/min after 10 minutes. In the presence of metoprolol, the coronary flow decreased from 11.8 ± 0.3 to 6.2 ± 0.5 ml/min (47%) and with diltiazem from 15.8 ± 0.6 to 8.6 ± 0.8 ml/min (46%) ($p < 0.025$ versus metoprolol). Hearts perfused with metoprolol generally had significantly lower flow rates than control hearts or hearts treated with diltiazem. It should be emphasized that these values of coronary flow refer to total flow, that is, the sum of ischemic and nonischemic zones.

Mechanical function (Fig. 1): To assess mechanical function, we measured cardiac output and calculated left ventricular work. In control hearts cardiac output decreased 45% from 59.5 ± 1.2 to 32.8 ± 1.2 ml/min immediately after coronary ligation and progressively declined over the ensuing 60 minutes of acute regional myocardial ischemia. In hearts perfused with metoprolol cardiac output was initially reduced 64% to 17.5 ± 2.5 ml/min ($p < 0.001$ versus control), but was then maintained at that level, so that 60 minutes after ligation the metoprolol-treated and control hearts had similar cardiac outputs. With diltiazem, cardiac output first decreased similarly to control by 43% to 30.9 ± 1.5 ml/min. However, these hearts showed no trend as did control hearts to go into cardiac failure, which in this model is defined as zero aortic output. Throughout the period of acute ischemia diltiazem maintained higher cardiac outputs than did metoprolol ($p < 0.001$).

Right atrial pacing to the heart rate of control hearts increased cardiac output and left ventricular work in both drug-treated groups, yet the differences remained the same. However, pacing of diltiazem-treated hearts for 60 minutes after coronary artery ligation resulted

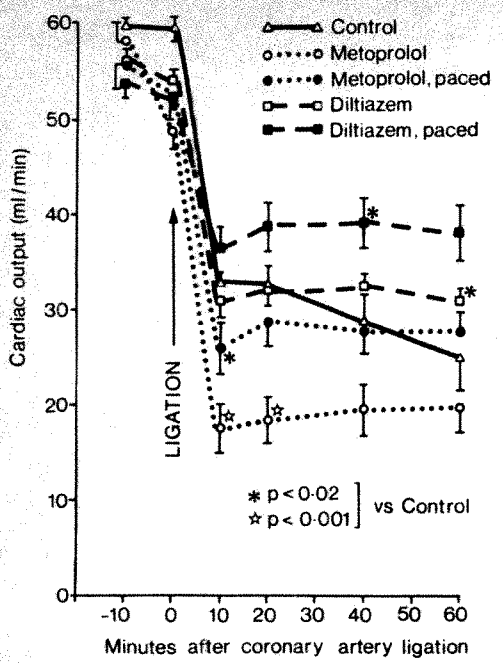

FIGURE 1. Effect of metoprolol 10^{-4} *M* (n = 10, paced n = 6) and diltiazem 4×10^{-7} *M* (n = 12, paced n = 6) on cardiac output. Diltiazem maintained higher cardiac output compared with metoprolol in unpaced ($p < 0.001$) as well as paced ($p < 0.01$) hearts throughout the duration of regional myocardial ischemia. Control n = 10.

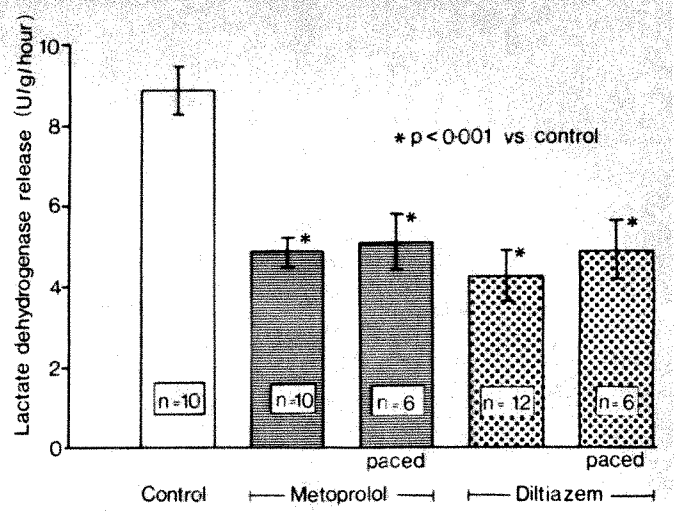

FIGURE 2. Cumulative release of lactate dehydrogenase over 60 minutes after coronary ligation with metoprolol (1×10^{-4} *M*) and diltiazem (4×10^{-7} *M*) in paced and unpaced hearts. The 2 compounds were equally effective in reducing enzyme release.

in significantly higher cardiac output and left ventricular work compared with control hearts (Table I).

Efficiency of cardiac work (Table I): Enhanced mechanical function resulting from diltiazem could increase oxygen demand, which theoretically could be deleterious to the ischemic heart. Therefore, we measured oxygen uptake and related it to left ventricular work, thereby calculating the efficiency of cardiac work. Coronary artery ligation reduced the efficiency of work in control hearts from 5.76 ± 0.23 to 4.63 ± 0.28 J/ml O_2 10 minutes after ligation and to 3.46 ± 0.45 J/ml O_2 60 minutes after ligation. Metoprolol either left the efficiency unchanged or decreased it (10 minutes after ligation, unpaced hearts). Diltiazem was associated with significantly higher efficiency values than metoprolol. However, this difference was not apparent if hearts were paced at equal heart rates.

Enzyme release (Fig. 2): In control hearts, production of acute regional myocardial ischemia resulted in a release of lactate dehydrogenase of 8.88 ± 0.60 U/h/g. This amount was reduced by about half by both metoprolol 1×10^{-4} *M* to 4.85 ± 0.38 U/h/g ($p < 0.001$) and by diltiazem 4×10^{-7} *M* to 4.25 ± 0.62 U/g/h ($p < 0.001$), reflecting preservation of cell integrity. Pacing of these hearts to the heart rate of control hearts (230 beats/min) did not alter this benefit and excluded a low heart rate as the mechanism of protection against the effects of ischemia.

To disclose possible mechanisms of protection the release of enzymes over the duration of the experiments is shown in Figure 3. The pattern of release appeared identical in all groups, therefore ruling out a major involvement of washout effects.

Tissue high energy phosphate content (Table II): Production of regional myocardial ischemia resulted in substantial depletion of high energy phosphates in the infarcting myocardium, with a decrease in adenosine triphosphate values to 0.60 ± 0.05 μmol/g fresh weight, but it also reduced adenosine triphosphate in the noninfarcting tissue (2.83 ± 0.30 μmol/g) as compared with control hearts without coronary ligation (3.40 ± 0.13 μmol/g) or the values found in retrograde perfused, "nonworking" hearts (5.08 ± 0.22 μmol/g). The contents of high energy phosphates in the infarcting myocardium were significantly preserved by both metoprolol and diltiazem. Of interest was that better mechanical function of hearts perfused with diltiazem was also associated with a higher adenosine triphosphate value (3.70 ± 0.13 μmol/g, $p < 0.05$) in the noninfarcting zone. It should be noted that the separation of tissue into ischemic and nonischemic zones is arbitrary, because of the graduation of coronary flow reduction to various

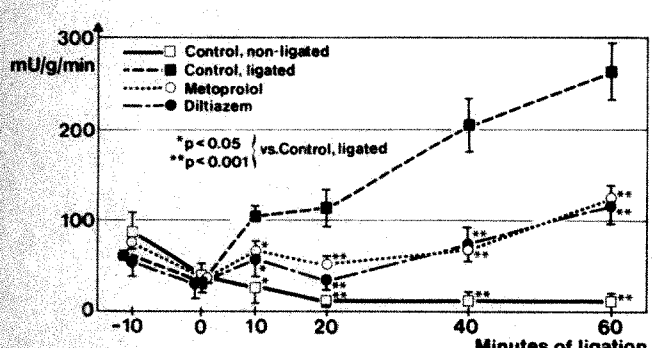

Figure 3. Release of lactate dehydrogenase over the time course of the experiments in coronary artery ligated (n = 10) and nonligated control hearts (n = 10) and hearts treated with metoprolol (n = 10) and diltiazem (n = 12).

TABLE II Tissue High Energy Phosphate Contents in the Infarcting and Noninfarcting Myocardium

zones of the heart in this model.[18] However, even considerable admixture of ischemic and nonischemic tissue in the assay samples could not explain the more beneficial effect of diltiazem than metoprolol on adenosine triphosphate levels. Only metoprolol improved phosphocreatine values in the ischemic zone.

Discussion

Cellular damage: The present investigation demonstrated that the beta-adrenoceptor antagonist metoprolol and the slow channel inhibitor diltiazem exert substantial protection against cellular damage on acutely infarcting myocardium. Similar results have been obtained for other compounds in each drug group,[8–16] although not consistently.[27–29] In the concentrations used, both interventions were equally effective in protecting myocardial cell integrity as assessed by enzyme loss in our preparation, and in addition preserved adenosine triphosphate in the infarcting tissue. Metoprolol, in addition, maintained phosphocreatine levels (Table II). However, the 2 agents exhibited opposing effects on the mechanical function of the heart after coronary ligation. Compared with diltiazem metoprolol caused deterioration of cardiac output and left ventricular work and efficiency immediately after production of acute myocardial ischemia.

Effect on mechanical function: Some studies in larger animals[30] have not revealed a depressant effect of beta-adrenoceptor antagonism on the mechanical function of the heart, but the compound used was practolol, which showed little cardiodepressant effect in some patient studies. A possible explanation for the relative absence of cardiodepressant effects by practolol is the intrinsic sympathomimetic activity that metoprolol does not possess. The concentration of metoprolol we used was probably higher than comparable doses of other beta-adrenoceptor antagonists used in most intact animal studies. In patients with acute infarction, intravenous metoprolol has also been used without precipitating left ventricular failure,[31] but the patients initially had no clinical features of congestive heart failure, and therefore probably had relatively small infarcts. Ligation of the left main coronary artery in rats results in an infarct involving almost all of the free wall of the left ventricle[32] and with a mean overall reduction of coronary flow to 57% of the preligation value.[18] Therefore, the more extensive size of the ischemic zone in this preparation probably produced a more significant cardiac deterioration than that found in most patients with acute infarction.

Improvement of the mechanical function of the heart mediated by diltiazem or other slow channel inhibitors has also been demonstrated in ischemic-reperfused preparations,[33–35] and has been further confirmed in the case of nifedipine by measurements of enhanced regional myocardial contractility in the ischemic myocardium of larger animals.[36] The effect on mechanical performance is considered to be related to the ability of these compounds to prevent deleterious intracellular calcium accumulation which can impair left ventricular contractile force and relaxation,[37] but improved coronary perfusion to the ischemic zone is likely to be another important factor.[36,38] Verapamil, in contrast, appears to depress regional myocardial contractility in the ischemic but not the nonischemic myocardium, whereas propranolol depresses both normal and ischemic myocardium.[39]

Preservation of cell integrity: A variety of mechanisms have already been proposed for the reduction of cellular damage in the acutely infarcting myocardium by beta-receptor antagonists and slow channel inhibitors.[3,5,8,12] Our experiments show that protection can be achieved when heart rate is not reduced.

Severity of cellular damage has been assessed by release of lactate dehydrogenase and the tissue content of high energy phosphates. It has to be noted that phosphocreatine, increased in the ischemic zone only by metoprolol, cannot be related to the extent of enzyme release[40] in contrast to the level of adenosine triphosphate.[41] It may be speculated that the elevated adenosine triphosphate content achieved by both metoprolol and diltiazem in ischemic myocardium could represent a specialized pool to which Bricknell and Opie[42] attributed a role in protecting the cell membrane.

Myocardial perfusion: In addition to the beneficial effects of diltiazem on the calcium homeostasis in the ischemic myocardium, its vasodilating activity has to be considered as a mechanism of protection.[36,38] Dilti-

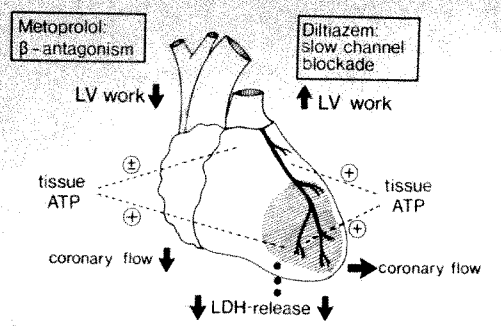

FIGURE 4. Comparative effects of metoprolol and diltiazem on acutely infarcting myocardium. Results are based on comparisons with control hearts in Tables I and II. ATP = adenosine triphosphate; LDH = lactic dehydrogenase; LV = left ventricle.

azem causes an increase in the blood flow in the peripheral zone of regional myocardial ischemia in the pig model.[43,44] Because no evidence for a coronary "steal" phenomenon[43–45] with diltiazem has been reported (in contrast to nifedipine[27]), one may suppose from our experiments that there was a redistribution, which was not clearly detectable by measuring the total coronary flow rate. By this, oxygen supply to the ischemic tissue would be improved and tissue acidosis diminished through washout of lactate and hydrogen ions. Excess hydrogen ions not only interfere with key reactions of metabolic pathways,[46] but also represent another factor that has been associated with impairment of the contractile function.[47].

Even though metoprolol exhibited reduced total coronary flow rates in our model, we cannot completely exclude a favorable redistribution of flow to the ischemic zone as found in the pig model.[48] A reduced washout of enzymes is possible in the case of metoprolol, so that enzyme release was falsely low; this sequence is rendered unlikely by increased values for high energy phosphates in the infarcting tissue. In addition, no facilitated washout is apparent for diltiazem (Fig. 2). Therefore, equal protection of cell integrity in the presence of significantly different flow rates suggests that mechanisms other than perfusion effects are involved in mediating preservation of ischemic myocardium. However, the opposing effects on mechanical function may possibly be related to the degree of myocardial perfusion.

Critique of the model: The isolated working rat heart with coronary artery ligation is a model with both advantages and disadvantages. The dynamic function of the heart can be studied under reproducible and controllable conditions,[18] whereas the severity of cellular damage induced by coronary artery ligation can be measured continuously and accurately by enzyme release.[20] A limitation of this preparation is that it fails to allow physiologic interaction of the heart with the peripheral circulation. The preparation is severed from the autonomic nervous system, quite unlike the situation in patients with infarction. The results obtained with this model cannot directly be extrapolated to the human heart, because heart rate, cardiac output, and coronary flow rates of the isolated rat heart are not comparable to those in man. The situation in any animal model when healthy coronary arteries are abruptly ligated may not be relevant to the much more complex coronary artery anatomy in patients when occlusive disease can antedate acute infarction by many years.

Another outstanding question is whether the beneficial effects of diltiazem administration before coronary artery ligation could also be achieved after the onset of the infarction process. However, most of the interventions initially applied before coronary artery occlusion[1] have also been effective within the first hours after coronary occlusion.[3]

The experimental concentrations of the 2 potentially cardioprotective agents are also open to criticism. With diltiazem, therapeutic concentrations in patients may reach 3×10^{-7} g/ml or 7.3×10^{-7} *M*.[5] Similar concentrations inhibit smooth muscle excitation coupling in the coronary arteries of the pig[2] and increase spontaneous cycle length in the isolated sinoatrial node in the rabbit.[5] Hence, the concentration (4×10^{-7} *M*) used in this study may well be of therapeutic importance in clinical practice. With metoprolol, a relatively large dose (10^{-4} *M*) was used that is well above the effective blood level of about 10^{-7} *M*.[49] At such high concentrations, cardioselectivity might well have been lost, hence tending to reduce coronary flow by an unopposed alpha-mediated vasoconstriction. However, because our study was based on a comparison of 2 similarly potent protective concentrations, 10^{-4} *M* of metoprolol was required to be as effective as 4×10^{-7} *M* of diltiazem.[23,24] This concentration of metoprolol was also required to antagonize isoproterenol 10^{-6} *M*. The local concentration of norepinephrine in ischemic myocardium is likely to be about 10^{-6} *M*.[40] At such very high concentrations, effects other than beta-antagonism, such as membrane protection, are likely to be relevant.

Such comparisons apply strictly to the isolated heart. In patients with acute myocardial infarction, circulating catecholamine concentrations (largely norepinephrine) are increased to about 5×10^{-9} *M*[50]; such concentrations of norepinephrine fail to increase enzyme release from the isolated rat heart.[40] Hence, our data may possibly have application in acute myocardial infarction even in the absence of added catecholamine stimulation.

Conclusion: The present study demonstrates that beta-adrenoceptor antagonism by metoprolol at large doses and slow channel inhibition by diltiazem at apparently therapeutic doses are equally effective in reducing cellular damage in the acutely infarcting myocardium but that there are opposing effects on the mechanical function of the heart. Diltiazem offered substantial cardioprotection in the presence of significantly better mechanical performance than metoprolol. Whereas metoprolol reduced cardiac output and left ventricular work compared with untreated control hearts, these variables appear to be influenced in a favorable way by diltiazem. Although our results were obtained in an isolated, perfused rat heart model, the principles involved could be of considerable importance in a clinical setting. Patients with acute myocardial infarction often have restricted ventricular function,

especially when the infarct is large, as in our model.[51] Further myocardial depression by beta-receptor antagonism could initiate cardiac decompensation and result in cardiogenic shock, whereas our studies raise the expectation that diltiazem could improve the mechanical function possibly by facilitating blood flow to the ischemic zone.

Although conclusions drawn from diltiazem may not apply to other slow channel inhibitors and evidence indicates that further experimental data in other models are required, both theoretical and experimental data suggest that slow channel blockade could become a more promising therapeutic approach than beta-adrenoceptor antagonism in minimizing myocardial infarct size (Fig. 4).

Inhibition of Hypoxic Pulmonary Vasoconstriction By Nifedipine

THOMAS KENNEDY, MD, MPH and WARREN SUMMER, MD

Nifedipine is a potent slow channel calcium antagonist and systemic vasodilator recently reported to attenuate hypoxic pulmonary vasoconstriction in man. Other systemic vasodilators have also been shown to attenuate hypoxic pulmonary vasoconstriction, but their effects in some species may be mediated by reflex beta-adrenergic discharge. We evaluated the effect of nifedipine on the relation between pulmonary arterial pressure and blood flow during hyperoxia (inspired partial pressure of oxygen [PO_2] 200 mm Hg) and hypoxia (inspired PO_2 50 mm Hg) in denervated ventilated pig lungs perfused in situ with the animal's own blood. Ten lungs were ventilated with alternating 15 minute periods of hyperoxia and hypoxia. Hypoxia shifted the pulmonary artery pressure (x axis)-blood flow (y axis) relationship to the right and decreased its slope, indicating vasoconstriction. Nifedipine, given as a 0.1, 1, or 10 μg/kg bolus into the pulmonary artery, caused a dose-dependent reduction of hypoxic pulmonary vasoconstriction. It is concluded that nifedipine is a potent pulmonary vasodilator acting locally within the lung and that it might be useful in the therapy of hypoxic pulmonary hypertension from chronic lung disease in man.

Pulmonary hypertension and resulting cor pulmonale account for 7 to 10% of all heart disease in the United States.[1] Probably the most important cause of cor pulmonale is hypoxic pulmonary hypertension associated with disorders such as chronic bronchitis and emphysema, bronchiectasis, cystic fibrosis, kyphoscoliosis, and chronic mountain sickness. The recommended therapy for hypoxic pulmonary hypertension is sufficient oxygen to relieve alveolar hypoxia and systemic hypoxemia.[2] However, supplemental oxygen is not always effective in relieving the elevated pulmonary artery pressure in these disorders[3] and is unquestionably expensive and inconvenient.

Recently, Simonneau et al.[4] demonstrated that nifedipine, a potent slow channel calcium antagonist and systemic vasodilator, inhibits hypoxic pulmonary vasoconstriction in patients with acute respiratory failure without deleterious effects on arterial oxygen saturation or delivery. Muramoto et al.[5] reported similar findings in a group of 9 patients with clinically stable chronic obstructive pulmonary disease. In their study subjects experienced an improvement in cardiac output and pulmonary vascular resistance at rest and during exercise, with a shift in pressure-flow curves to the right, indicating a decrease in pulmonary pressure at similar levels of cardiac output occurring when subjects were treated with nifedipine as opposed to placebo. Arteriovenous oxygen content decreased whereas arterial oxygen saturation did not change.

These results indicate that nifedipine is potentially useful as a vasodilator to reduce the afterload of the right ventricle in cor pulmonale resulting from hypoxic pulmonary hypertension, but shed no light on whether nifedipine acts locally within the lung or indirectly through the sympathetic nervous system. Minoxidil reduces hypoxic pulmonary hypertension, but its effect in hypoxic cattle is prevented by beta-adrenergic blockade.[6] Nifedipine also stimulates a reflex sympathetic discharge.[7,8] To determine whether nifedipine locally or reflexly inhibits hypoxic pulmonary hypertension, we investigated the ability of increasing doses of nifedipine to reverse the pulmonary hypoxic response in isolated perfused pig lungs void of any sympathetic innervation.

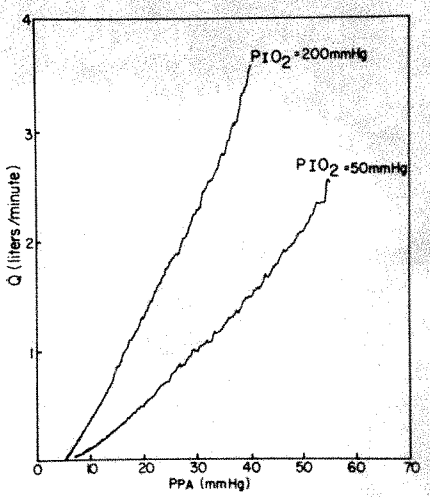

FIGURE 2. Typical pulmonary pressure (Ppa)-flow (Q̇) curves during hyperoxia (PIO_2 = 200 mm Hg) and hypoxia (PIO_2 = 50 mm Hg).

Methods

Experimental preparation: The pig was chosen as the experimental animal because its pulmonary circulation responds vigorously to hypoxia.[9] Pigs weighing 20 to 40 kg were anesthetized with intravenous pentobarbital sodium and ventilated through a tracheal cannula with room air by a respirator. After mid-sternal thoracotomy the animal was given 10,000 U of heparin intravenously, the left atrium was cannulated, and the animal was then bled a volume of approximately 1,000 ml into a Plexiglas® reservoir (Fig. 1). This volume of blood was supplemented with 6% dextran in normal saline solution to yield a total perfusate volume of 1,500 ml. The pulmonary artery was then cannulated and the root of the aorta was tied off. During perfusion, blood entered the left atrium, drained by gravity into the reservoir, and was then pumped with a roller pump (Sarns model 3500) through a heat exchanger, blood filter, and electromagnetic flow probe to the pulmonary artery. Except during pressure-flow determinations, blood flow was constant at 1.0 liter/min. Pulmonary artery and left atrial pressure was measured with strain gauges zero-referenced to the level of the right atrioventricular valve. Left atrial pressure was maintained at −20 mm Hg by adjusting the level of the reservoir. After perfusion was begun, the lungs were ventilated with a normoxic normocapnic gas mixture at a rate of 6 to 7 breaths/min and a tidal volume of 400 ml. End-expiratory tracheal pressure was kept at 3 to 4 cm of water to prevent alveolar collapse. Airway oxygen and carbon dioxide tensions were measured with gas analyzers (Beckman). Blood temperature was kept between 38.5 and 39.5°C. Blood gas tensions and pH were measured by standard electrode techniques (Radiometer BMS3 MK2). Blood PCO_2 was 35 to 40 mm Hg and pH 7.35 to 7.45.

Hyperoxia and hypoxia: After a stabilization period of 60 minutes, the lungs were exposed alternately to hyperoxic and hypoxic gas mixtures. During hyperoxia the inspired gas consisted of 38.2% oxygen, 5.4% carbon dioxide, and 66.4% nitrogen. During hypoxia it consisted of 7% oxygen, 5.4% carbon dioxide, and 87.6% nitrogen. This level of hypoxia was chosen because in the pig it causes maximal steady state pulmonary vasoconstriction.[9] When pulmonary artery pressure stabilized, the pulmonary artery pressure-flow relation was determined by stopping ventilation in end-expiration, increasing pump flow to fill the standpipe (Fig. 1) and, when pulmonary artery pressure was stable, suddenly stopping the pump to allow blood to flow by gravity from the standpipe through the lungs into the reservoir until zero flow was achieved. During this procedure, an x-y recorder was used to record the relation between pulmonary artery pressure (x) and flow (y). Measurement of the relation between pulmonary artery pressure and blood flow has previously been used by a number of investigators[10–12] to demonstrate the state of pulmonary vascular resistance over a wide range of possible blood flows, thus avoiding possible pitfalls of measuring a single value of pulmonary artery pressure at constant flow. Figure 2 illustrates typical curves recorded during normoxia and hypoxia. During hypoxia, the curve is shifted to the right and decreased in slope, indicating vasoconstriction. Changes in these pressure-flow relations were quantified by determining the pulmonary artery pressure at a flow of 1 liter/min directly from the record curve.

Nifedipine administration: Two groups of animals (n = 5 in each) were studied. All lungs underwent 300 minutes of perfusion. Pulmonary artery pressure-flow relations were determined at the end of each period of hyperoxia and hypoxia. After determination of a curve, the inspired gas mixture was changed and time was allowed for stabilization of pulmonary artery pressure before another curve was recorded. Generally, stabilization occurred within 15 minutes. The experimental group received nifedipine into the pulmonary artery in injections of 0.1, 1, and 10 μg/kg at perfusion times of 120, 180, and 240 minutes. Nifedipine in a concentration of 100 μg/ml was prepared under conditions of reduced light in a vehicle consisting of 14 ml of polyethylene glycol, 22 ml of absolute ethanol, and 64 ml of water, and was diluted with appropriate volumes of vehicle to achieve an injection volume of 0.1 ml/kg. The control group received injections of 0.1 ml/kg of vehicle alone into the pulmonary artery at perfusion times of 120, 180, and 240 minutes. Blood pH was checked after each administration of drug to confirm that it had not changed.

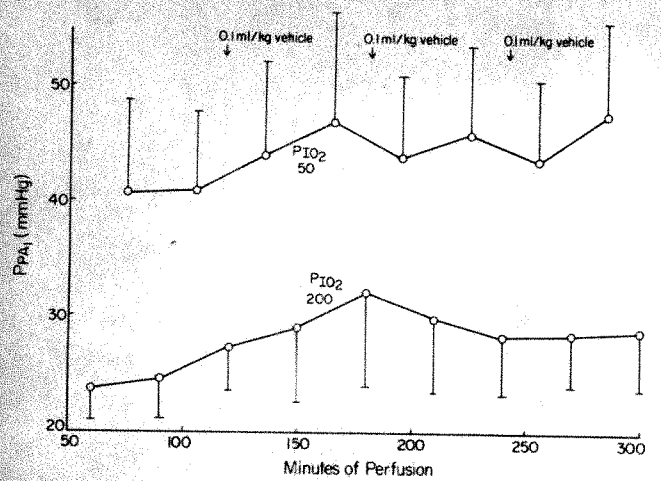

FIGURE 3. Pulmonary artery pressure of control animals (n = 5) at a blood flow of 1 liter/min (Ppa_1) during alternating periods of hyperoxia (PIO_2 = 200 mm Hg) and hypoxia (PIO_2 = 50 mm Hg) ventilation. **Open circles** represent mean PPa ± 1 standard error of the mean.

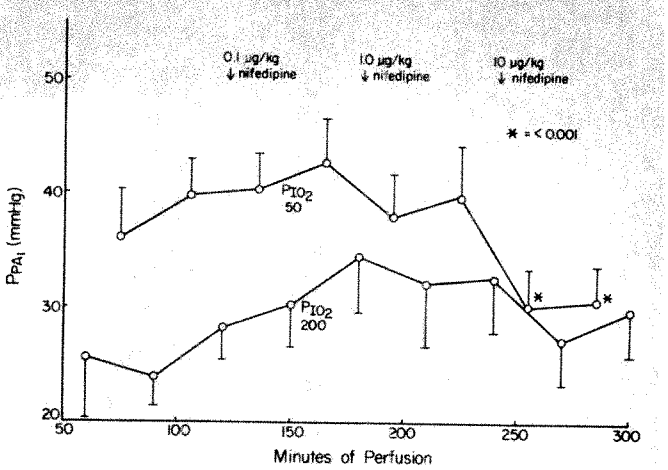

FIGURE 4. Pulmonary artery pressure of nifedipine-treated animals (n = 5) at a blood flow of 1 liter/min (Ppa_1) during alternating periods of hyperoxia (PIO_2 = 200 mm Hg) and hypoxia (PIO_2 = 50 mm Hg) ventilation. **Open circles** represent mean PPa ± 1 standard error of the mean.

Values for pulmonary artery pressure at a flow of 1 liter/min (Ppa_1) during hyperoxia and hypoxia for control and experimental animals and differences between Ppa_1 for each hyperoxic and its subsequent hypoxic value for control and experimental animals were compared using a 2-way analysis of variance. When F ratios achieved a 0.05 level of significance, a protected least significant difference was computed according to the method of Fisher.[13]

Results

Control versus nifedipine: Results for control animals are shown in Figure 3, in which mean values of pulmonary artery pressure at a blood flow of 1 liter/min (Ppa_1) for the 5 animals are plotted for each set of hyperoxic and hypoxic curves determined during the 300 minute perfusion. Both hypoxic and hyperoxic responses tended to reach a relative plateau after 120 minutes. Mean values of pulmonary artery pressure at a flow of 1 liter/min during hyperoxia and hypoxia for nifedipine-treated animals are shown in Figure 4. A decrease in mean pulmonary artery preasure at a flow of 1 liter/min was not seen until after the 1.0 µg/kg dose of nifedipine. After the 10 µg/kg dose there was nearly complete abolition of hypoxic vasoconstriction with some transient decrease in mean Ppa_1 during hyperoxia as well.

Mean inhibition of the hypoxic pressor response (mean ΔPpa_1) as a function of dose of nifedipine (Fig. 5). For each animal, ΔPpa_1 was determined as the difference between pulmonary artery pressure at a blood flow of 1 liter/min during hyperoxia at perfusion times of 90, 150, 210, and 270 minutes, and the subsequent stable pulmonary artery pressure at 1 liter/min flow during hypoxia at perfusion times of 105, 165, 225, and 285 minutes, respectively, for control and increasing doses of nifedipine. Thus ΔPpa_1 corresponds to the difference between the last hyperoxic and hypoxic response during each study period before subsequent administration of the next larger dose of drug and was chosen to allow the respective doses of drug to circulate within the perfusion system so that drug effect could stabilize. The mean ΔPpa_1 of control animals remained stable over all 4 study periods. The mean ΔPpa_1 for nifedipine-treated animals decreased progressively with logarithmically increasing doses of drug, so that at a dose of 1 µg/kg there was 50% inhibition of the hypoxic response, and at a dose of 10 µg/kg nearly complete inhibition occurred.

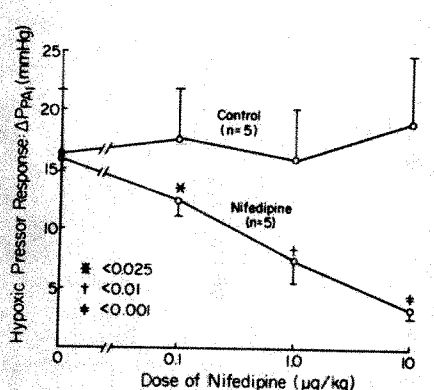

FIGURE 5. Hypoxic pressor response (ΔPpa_1) in control (n = 5) and nifedipine-treated (n = 5) animals as a function of dose of nifedipine. Each **open circle** represents mean ΔPpa_1 ± 1 standard error of the mean.

Discussion

Hypoxia is an effective and consistent stimulus to pulmonary hypertension.[14] However, debate still exists as to whether hypoxia exerts its effects directly on pulmonary vascular smooth muscle or indirectly through mediator release within the lung.[15] The results of our study indicate that nifedipine is a potent inhibitor of the pulmonary hypoxic response, independent of the

reflex adrenergic discharge. However, we cannot conclude where within the lung itself nifedipine's action is located.

Effect of slow channel calcium antagonists on pulmonary hypoxic response: Blockade of the pulmonary hypoxic response by slow channel calcium antagonists was first reported in 1976 by McMurtry et al.,[16] who used verapamil to inhibit hypoxic pulmonary hypertension in isolated rat lungs. These investigators suggested that hypoxia might act directly to depolarize pulmonary vascular smooth muscle, and that verapamil inhibited the transmembrane flow of calcium into the cell and prevented activation of the contractile machinery. Where and how this supposed inhibition of transmembrane calcium flux works in vascular smooth muscle is unclear. It is even unclear whether verapamil and nifedipine affect calcium flux in the same way. In cardiac muscle, where contraction is associated with changes in calcium flux initiated by cellular membrane depolarization, verapamil alters the kinetics of calcium flux, whereas nifedipine affects total calcium conductance, presumably by differential effects on the two gates of the calcium channel of cardiac tissue.[17] In vascular smooth muscle, however, contraction was recently found to be dependent on pharmacomechanical coupling, that is, contraction that is induced by the binding of an exogenous agent such as norepinephrine to a receptor, precipitating changes in calcium flux not necessarily associated with changes in transmembrane potential.[18] We are not aware of any work conclusively pointing to differential sites of action of nifedipine and verapamil on calcium flux in vascular smooth muscle. Until such work is available, the demonstration that both nifedipine and verapamil inhibit the pulmonary hypoxic response does not add to our basic understanding of the potential subcellular mechanisms in smooth muscle that might be operative in hypoxic pulmonary vasoconstriction.

Site and mechanism of inhibition of pulmonary hypoxic response: It is not even certain that slow channel calcium antagonists are working only at the level of vascular smooth muscle to inhibit the pulmonary hypoxic response. It was previously suggested that the pulmonary hypoxic response is induced by mast cell release of vasoactive substances,[19,20] and mast cells are strategically dispersed along the course of the pulmonary resistance vessels.[21] The observation that both nifedipine and verapamil inhibit pulmonary hypertension in cat lobes infused with a stable prostaglandin endoperoxide[22] indicates that these agents are able to block pharmacomechanical coupling in pulmonary vascular smooth muscle. In preliminary in vitro experiments, some investigators[23] claimed that nifedipine blocks the release of platelet-activating factors and slow reactive substances, and reduces release of acid phosphatase and glucuronidase from human polymorphonuclear leukocytes induced by ionophore, zymozan, or zymozan-complement complexes. If these results are confirmed and shown true for mast cells as well, it is possible that nifedipine might be blocking the calcium-dependent release of some vasoactive substance released locally within the lung in response to hypoxia.

Clinical implications: Regardless of the mechanism of subcellular action, the demonstration that a vasodilator works locally within the lung to attenuate hypoxic pulmonary hypertension may be considerably important in predicting any ultimate benefit to patients with pulmonary hypertension given the agent as therapy. Nitroglycerin was explored as a vasodilator in patients with pulmonary hypertension from chronic obstructive pulmonary disease, and was demonstrated to decrease mean pulmonary artery pressure.[24] However, nitroglycerin accomplishes this only by altering venous capacitance to decrease right ventricular preload, without affecting pulmonary vascular resistance. Thus, a decrease in mean pulmonary artery pressure is achieved at the expense of a decrease in cardiac output and oxygen delivery. Bishop et al.[25] recently reported that both nifedipine and minoxidil inhibit the pulmonary hypoxic response in intact dogs. However, minoxidil was previously demonstrated[6] to lose its effectiveness as a pulmonary vasodilator in hypoxic cattle after beta-adrenergic blockade. Despite the fact that nifedipine also elicits a reflex beta-adrenergic discharge,[7,8] our results clearly document that pulmonary vasodilation from nifedipine in a denervated pig lung is void of any potential for reflex sympathetic activity. Thus, if the human circulation responds similarly to the hypoxic bovine pulmonary circulation, subjects with lung disease might not have pulmonary vasodilation from minoxidil if they are also receiving cardioselective beta-blockers or centrally acting antihypertensive agents that decrease sympathetic outflow, but their response to nifedipine might be expected to remain intact.

To be useful in a clinical setting, nifedipine would have to be proved efficacious in producing a decrease in pulmonary vascular resistance without markedly altering redistribution of blood to poorly ventilated regions so as to not worsen hypoxemia. We were unable to address this question because the perfusate reservoir of our preparation was open to air, but in a recent report, Bishop et al.[25] found that nifedipine increased venous admixture in intact dogs. However, Simonneau et al.[4] found only a slight (45 ± 2 to 42 ± 2 mm Hg) although statistically significant change in arterial PO_2 in a group of 13 patients with acute respiratory failure given nifedipine, and Muramoto et al.[5] show no change in arterial PO_2 either at rest or during exercise in 9 subjects with chronic obstructive pulmonary disease given the agent. This lack of clinically significant desaturation after the administration of nifedipine in man might be explained on the basis of an increase in cardiac output and a decrease in arteriovenous oxygen content, as occurred in Muramoto's patients,[5] were it not for the fact that mixed venous PO_2 did not change in subjects studied by Simonneau et al.[4] Thus, the ventilation-perfusion relations that follow nifedipine administration may be unusually complex. Nevertheless, these agents offer promise in the treatment of patients with cor pulmonale in which low cardiac output is a factor limiting clinical well-being.

Acknowledgment

We gratefully acknowledge the assistance of Jimmie Sylvester, MD, in the design and analysis of this study, David Poorvin, MD, of Pfizer Laboratories for providing nifedipine, and Janet Hupp and Ernestine Mikeal for help in the preparation of the manuscript.

CHANGING
ANGINA
THERAPY
Calan™
(verapamil HCl)
TABLETS
80 mg and 120 mg
The Prototype
Calcium Antagonist
Please see the following page for a brief summary
of the complete prescribing information.

Calan™ TABLETS
80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction < 30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR < 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

EDITED BY

DEAN T. MASON, M.D.
Professor of Medicine and Physiology
Chief, Cardiovascular Medicine
University of California at Davis
School of Medicine and University Medical Center
Davis and Sacramento, California
Editor-In-Chief, AMERICAN HEART JOURNAL

JOHN J. COLLINS, JR., M.D.
Professor of Surgery

Harvard Medical School
Brigham and Women's Hospital
Boston, Massachusetts

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Sample Table of Contents:

Section 1 - Stable Angina Pectoris and Asymptomatic Coronary Disease

Section 2 - Variant Angina Pectoris

Section 3 - Unstable Angina Pectoris

Section 4 - Acute Myocardial Infarction

Section 5 - Myocardial Preservation

Section 6 - Pharmacologic and Related Approaches to Coronary Dilatation

Section 7 - Percutaneous Transluminal Coronary Angioplasty

Section 8 - Intracoronary Thrombolysis in Evolving Myocardial Infarction

Section 9 - Long-Term Achievements of Myocardial Revascularization by Medical and Surgical Therapy

recious than platinum.

The Siemens-Elema ACE™ (**A**ctivated **C**arbon **E**lectrode) carbon tip pacing leads utilize the unique properties of vitreous carbon.

We are the sole manufacturer of this material which, thanks to minor tissue reaction, gives significantly low polarization voltages.

Clinical experience has shown low chronic thresholds, which reduce the risk of exit block.

Pacemaker longevity can be increased through reduction of output energy, consistent with the reduced threshold of the ACE™ electrode.

CAUTION:
Read Physicians Product Manual (ME 372/5713.406) for proper implantation procedures and possible complications.

POSSIBLE COMPLICATIONS
An implanted pacemaker electrode is in direct contact with the myocardium. Equipment operating on alternating current can present a risk of causing fibrillation, if it is not satisfactorily grounded, or if it is faulty. Even battery-operated instruments connected to the electrode can be dangerous, if they are in contact with the above-mentioned equipment.
The following are examples of other complications that can arise:
- Intermittent or continuous "exit block", or detection problems, caused, for example, by dislodgement of the tip of the electrode, perforation of the myocardium, or insulation defects.
- Infection at the point of connection to the vein, which can require surgical treatment.

ANGINA
INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.
Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.
INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.
Please see following page for Brief Summary of Prescribing Information.

INDERAL®
(PROPRANOLOL HCl)
THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE. In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA. Propranolol may prev the appearance of premonitory signs and symptoms (pulse rate and pressure cha acute hypoglycemia, especially in patients with labile diabetes. A precipitous elev blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY. Safe use in human pregnancy not established. Embryoto effects have been seen in animals at doses about 10 times the maximum recomme human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be clo observed if propranolol is administered, since it may occasionally produce hypote and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hy sion.

Observe laboratory parameters at regular intervals. Use with caution in patients impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; h sion, paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thron topenic purpura. *Central Nervous System*: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue, reversible mental depressio gressing to catalonia, visual disturbances, hallucinations, an acute reversible synd characterized by disorientation for time and place, short term memory loss, emotior lability, slightly clouded sensorium and decreased performance on neuropsychom *Gastrointestinal*: nausea, vomiting, epigastric distress, abdominal cramping, diarrh constipation; mesenteric arterial thrombosis, ischemic colitis. *Allergic*: pharyngitis agranulocytosis, erythematous rash, fever combined with aching and sore throat, la spasm and respiratory distress. *Respiratory*: bronchospasm. *Hematologic*: agranu tosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous*: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous mer and conjunctivae reported for a beta-blocker (practolol) have not been conclusively ciated with propranolol. *Clinical Laboratory Test Findings*: Elevated blood urea leve patients with severe heart disease; elevated serum transaminase, alkaline phospha lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imp with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NI 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NI 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprin "INDERAL 20" contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0 0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0 0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and impr with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NI 0045-0424-81) and 1,000 (NDC 0045-0424-91). Also in unit dose package of 100 (N 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and impr with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NI 0046-0428-81) and 1,000 (NDC 0045-0428-91). Also in unit dose package of 100 (N 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-

Store at room temperature (approximately 25° C).

ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

To reduce the risk of potentially fatal arrhythmias in such patients

QUINAGLUTE® 324 mg DURA-TABS®

(quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

QUINAGLUTE® (quinidine gluconate) DURA-TABS®
INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.
2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.
3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.
4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.
5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.
7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.
8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

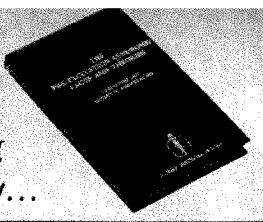
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Effects of Angiographic Contrast Medium on Isolated Canine Coronary Arteries

HECTOR LARDANI, MD, GUSTAVO RINALDI, MD,* and HORACIO CINGOLANI, MD

In isolated canine coronary arteries previously contracted by high potassium concentration, angiographic contrast medium decreased active tension by 61 ± 2%. The relaxant effect was dose dependent and was not prevented by beta-blockade with d-l-propranolol (10^{-5} *M*). This effect was similar to that obtained with nitroglycerin (10^{-6} *M*), and further relaxation was evident when this vasodilator was administered after exposure to the contrast medium. When arteries were precontracted by alpha-receptor stimulation with norepinephrine (10^{-5} *M*) at normal potassium concentration, a maximal relaxation of 83 ± 6% was elicited after exposure to contrast medium. The relaxant effect could not be reproduced by a similar increase in osmolarity brought about by addition of sucrose. When arterial strips were processed by radioimmunoassay for dosage of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) after the relaxing action of the contrast medium occurred, a decrease in cAMP from 2.61 ± 0.86 to 0.63 ± 0.1 pmol/mg protein ($p < 0.05$) was observed, whereas no significant changes in cGMP were detected. These nucleotides do not appear to be involved in the relaxant effect of the dye in the same way as they are when relaxation is elicited by some other coronary vasodilators.

Selective coronary arteriography is being widely used for diagnostic purposes since early 1960.[1] However, despite some studies with contrast agents showing increased coronary flow after its injection[2,3] and preliminary reports on the effect of the contrast medium on isolated coronary arteries,[4,5] information about this subject is scarce.

Almost invariably, vasodilators are given during coronary arteriography to better define the caliber of the coronary arteries and collateral circulation and sometimes to study regional motion of the left ventricle. More recently provocative maneuvers such as cold pressor test,[6] hyperventilation,[7,8] and ergonovine administration[9] are being used to induce coronary spasm. These maneuvers are usually performed after a set of coronary arteriograms has been obtained for comparison. Obviously, in this "control" set the arteries are already exposed to the action of the contrast medium. It is then of interest to know the primary effect of the contrast agent on the coronary smooth muscle. A potent vasodilator effect induced by the contrast medium might perhaps mask the action of a vasodilator or attenuate a vasoconstrictor stimulus according to their respective intensity and mechanism of action.

The present investigation was therefore designed to study the effects of a largely used contrast agent on the coronary smooth muscle and to elucidate its possible mechanism of action.

Methods

Mongrel dogs of either sex were anesthetized with pentobarbital sodium (35 mg/kg) and killed by rapid excision of the heart. Sections of the circumflex or anterior descending branches of the left coronary artery or both were obtained and stripped of loose fat and connective tissue. Helical strips (2 to 3 mm wide, 0.2 to 0.3 mm thick, and 10 to 12 mm long) were cut and vertically mounted in a 15 ml muscle bath filled with Krebs-Henseleit (K-H) solution (Fig. 1). The composition of the solution was (in m*M*/liter): NaCl 118, KCl 5.32, NaH_2PO_4 1.54, $MgSO_4$ 1.19, $NaHCO_3$ 24.9, $CaCl_2$ 2.53, and EDTA 0.01; it was aerated with 5% carbon dioxide in oxygen (pH 7.42 ± 0.01) and maintained at 37° C. The inferior end of the strip was attached to a stationary rod and the other end was suspended from a Grass FTO3C force transducer whose output was driven to an oscillographic recorder. A resting tension of 2 g was obtained by stretching the strips, and they were allowed to equilibrate for 1 hour. A contracture was then elicited by replacing the standard K-H solution by another containing 35 m*M* potassium chloride and kept isoosmotic by equivalent reduction of the sodium chloride concentration.

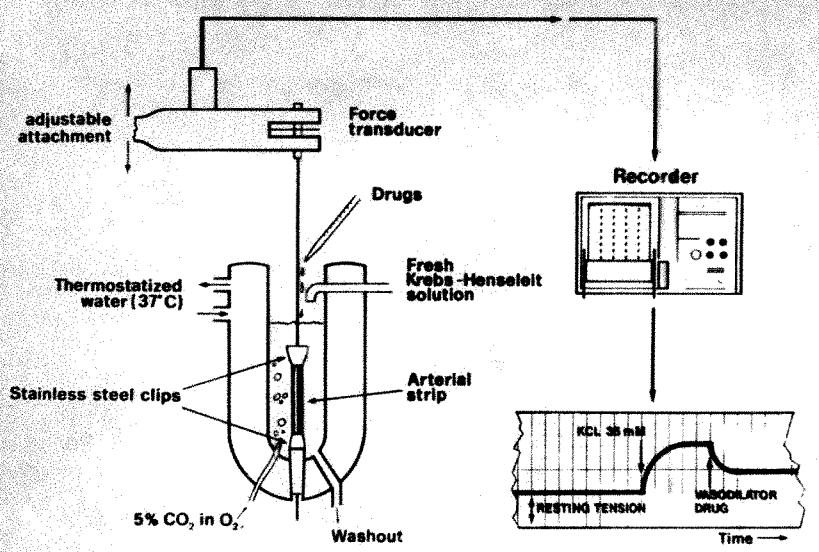

FIGURE 1. Experimental preparation used in the experiments. **Lower right,** schematic typical record.

After the preparation stabilized, the following groups of experiments were performed: *Group I* ($n = 33$): The time course of the contracture was studied for 1 hour and used as the control for the remaining mechanical studies.

Group II ($n = 15$): Cumulative dose-response curves for the contrast agent were performed, increasing its concentration to 33% vol/vol in 3% steps. Tension was allowed to stabilize after each dose, usually taking less than 5 minutes. Beta-blockade with d-l-propranolol 10^{-5} *M* was performed in 8 of these experiments before administration of the contrast agent. This dose of d-l-propranolol was shown to produce significant blockade in similar preparations.[10]

Group III ($n = 8$): Sucrose was added to the bath to obtain an increase in osmolarity comparable to that present when the 15% vol/vol dose of contrast medium was tested. This dose of dye was found to be most effective in the previous group.

Group IV ($n = 10$): After 30 minutes of beta-blockade with d-l-propranolol 10^{-5} *M*, contracture was elicited by the addition of norepinephrine 10^{-5} *M* to the normal K-H solution, and maintained for 5 minutes. After washing and returning to baseline, the entire procedure was repeated, and once contracture had stabilized the contrast agent was added to the bath in a 15% vol/vol dose and its effect studied.

After further washout, the ability to contract in response to the same norepinephrine challenge was assessed in 8 strips. *Group V* ($n = 22$): Nitroglycerin 10^{-6} *M* was added to the bath, and the relaxant effect was followed along time to compare it with the effect of the single dose of dye studied in group IV. The relaxant action of nitroglycerin was also studied in arterial strips previously exposed to a 15% vol/vol dose of contrast agent.

Group VI ($n = 31$): A single dose of 15% vol/vol of the contrast agent was added to the bath, and after the typical effect was recorded the strip was clamp-frozen, pulverized, and stored at −85°C. Dosage of adenosine 3′,5′-monophosphate (cAMP) and guanosine 3′,5′-monophosphate (cGMP) was performed with a modification of the radioimmunoassay method described by Steiner et al.[11,12] The protein content of the samples was calculated with the method of Lowry et

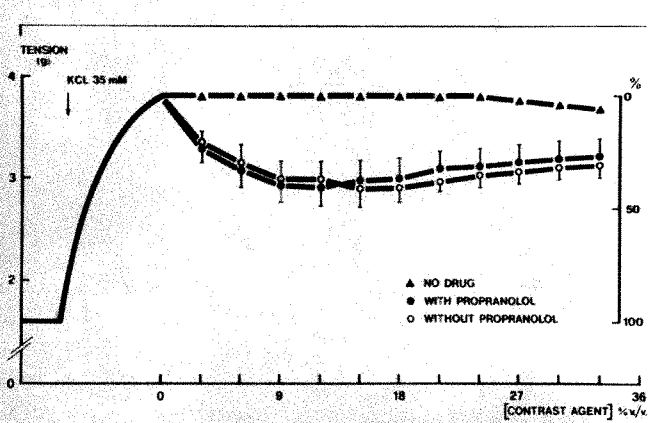

FIGURE 2. Relaxant effect of contrast agent on precontracted arterial strips, with and without beta-blockade. Time between doses was usually 5 minutes.

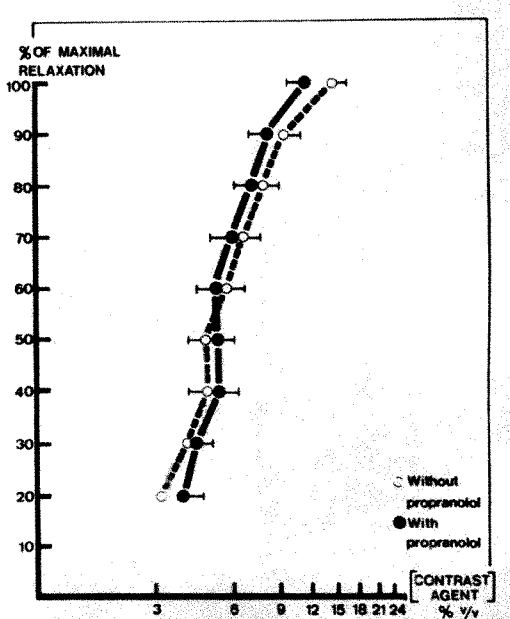

FIGURE 3. Dose-effect relation of the contrast agent, with and without beta-blockade. Drug concentration is on a logarithmic scale.

al.[13] and the cAMP and cGMP contents were expressed in picomoles per milligram of protein. Twenty-eight strips processed in the same way but without the addition of contrast medium were taken as the control in this group.

Drugs: The contrast medium was used as directed by the manufacturer for direct diagnostic use in man. Its composition (g/100 ml) was: sodium diatrizoate 10, meglumine diatrizoate 66, EDTA 0.01, and sodium biphosphate (Triyosom C, Gobbi Laboratories, Argentina) 0.012. This solution was warmed to 37° C before its addition to the bath. Nitroglycerin solution was obtained by diluting in K-H solution standard commercial tablets crushed to powder, and was freshly prepared each day.

The results were calculated as percentages of their own controls and expressed as mean ± standard error of the mean (SEM). Student's *t* test for unpaired observations and analysis of variance were used to analyze the results. Differences were considered statistically significant with $p < 0.05$.

Results

The K-H solution with 35 m*M* potassium chloride concentration elicited a contracture of 1.86 ± 0.2 g in the control experiments. The tension remained unaltered during the first 40 minutes, and a progressive but not statistically significant decrease was observed thereafter, reaching 95 ± 5% of control values at 1 hour (Fig. 2).

Cumulative doses of the contrast medium ranging from 3 to 15% vol/vol produced a dose-dependent relaxation in all the strips (Fig. 2). The maximal effect (41 ± 6%, $p < 0.05$) was obtained with the 15% vol/vol dose (Fig. 2 and 3). Higher concentrations of the dye had a smaller relaxant effect, but this action was still significant at the highest (33% vol/vol) dose employed (30 ± 5%, $p < 0.05$). Pretreatment of the strips with d-l-propranolol 10^{-5} *M* did not alter the previously described relaxant effect (Fig. 2 and 3). When the concentration of dye was elevated to 15% vol/vol in 1 step instead of following the progressive method described, a greater relaxation (61 ± 2%) was observed.

When an increase in osmolarity similar to the one produced by the 15% vol/vol dose of contrast medium was brought about by the addition of sucrose, a slight but significant relaxation (11 ± 2%) was observed. However, this effect was significantly smaller than the 61 ± 2% produced by the contrast medium at the same time (Fig. 4). This figure also shows the time course of the contrast agent action. Its effect, already evident a few seconds after its addition to the bath, was found significant at 20 seconds, and reached its maximal effect at 1 minute.

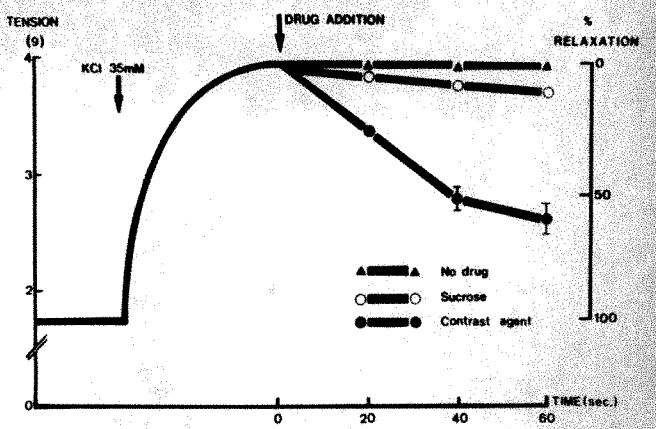

FIGURE 4. Comparative time course of the relaxant effects of the contrast agent and a similar increase in osmolarity brought about by the addition of sucrose to the bath.

In strips precontracted by alpha-receptor stimulation and at normal (5.32 m*M*) potassium chloride concentration the addition of contrast agent in a 15% vol/vol dose elicited a relaxation of 45 ± 5% after 20 seconds, reaching 83 ± 6% after 5 minutes (Table I). This relaxation was sustained, and the strips retained their ability to contract in response to a norepinephrine challenge after washing.

In another set of experiments the relaxing properties of the contrast medium were compared with those exhibited by a classic vasodilator such as nitroglycerin. A single dose of 10^{-6} *M* produced a maximal relaxation

of 61 ± 5%, whereas a single dose of the dye (15% vol/vol) produced a maximal effect of 62 ± 5%; the 2 values did not differ significantly (Fig. 5). This figure also shows the additive effect that was evident when nitroglycerin was administered after maximal relaxation with the contrast agent had already been obtained. This intervention produced a relaxation of 74 ± 5%, significantly greater than the one elicited by the contrast agent alone.

After maximal relaxation obtained by addition of the contrast agent, intracellular cAMP levels were significantly decreased from 2.61 ± 0.86 to 0.63 ± 0.1 pmol/mg protein. Cyclic GMP levels showed no significant variations under identical conditions, being 17.6 ± 2.9 pmol/mg protein in the control experiments and 20.9 ± 2.7 pmol/mg protein after the relaxing action of dye (Fig. 6).

Discussion

Little information is available on the primary effect of contrast medium on vasomotion of isolated coronary arteries. Our experiments demonstrated a potent relaxing effect, evident a few seconds after administration of the drug. When cumulative doses were used, the maximal relaxant effect was obtained with the 15% vol/vol dose (41 ± 6%). Higher concentrations of the drug showed a diminished relaxing action, being nevertheless significant at the highest dose tested (33% vol/vol). In another set of experiments in which a single dose of 15% vol/vol was used, the relaxing effect obtained was more marked (61 ± 5%). This difference in the intensity of relaxation might be related to a fade out in the effect of the initial doses when the cumulative method was employed.

A better estimation of the magnitude and chronology of this relaxing effect was attempted by performing experiments comparing the action of the contrast medium with that of a classic vasodilator (nitroglycerin). The intensity of relaxation was similar for the 15% vol/vol dose of contrast agent and for a dose of nitroglycerin large enough to mimic the concentration obtained by sublingual administration in clinical use. With respect to the time course of their actions, the contrast agent needed approximately twice the time required by nitroglycerin to reach the half maximal effect.

Experiments with beta-blockade with d-l-propranolol ruled out the hypothesis that the relaxing mechanism of the contrast medium was the stimulation of the beta receptor.

In experiments with sucrose at a concentration high enough to produce an increase in osmolarity similar to that present when the 15% vol/vol dose of dye was tested, a slight but significant relaxant effect was observed. However, because this action was significantly smaller than that observed with the contrast agent alone, hyperosmolarity by itself does not explain our findings.

To assess the relaxant effect of any pharmacologic agent on smooth muscle it must be previously contracted. Active tension development can be elicited by depolarization with high potassium solutions,[14,15] alpha-receptor stimulation,[16,17] or stimulation by other agents.[18–20] In our experiments the relaxant effect of the contrast agent was demonstrated in arteries precontracted either by high potassium solutions or by alpha-receptor stimulation with norepinephrine in solutions with normal potassium chloride concentration. These findings are interesting because the increase in the intracellular Ca^{2+} concentration, which is a prerequisite for active tension development, is probably achieved in two different ways by these two forms of stimulation. High potassium solutions (35 to 40 m*M*) cause an increased influx of Ca^{2+} through the cell membrane[14,15] whereas norepinephrine contraction appears more dependent on releasable intracellular

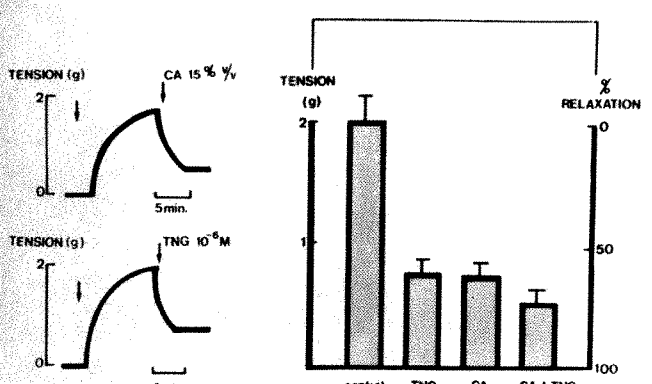

FIGURE 5. Top left, typical experiment showing the relaxant effect of nitroglycerin (TNG). **Bottom left,** typical experiment showing the relaxant effect of contrast agent (CA) and the additional relaxation obtained with the administration of nitroglycerin. **Left arrow** indicates potassium chloride concentration of 35 m*M*. **Right,** comparative effect of nitroglycerin, contrast agent and the addition of both.

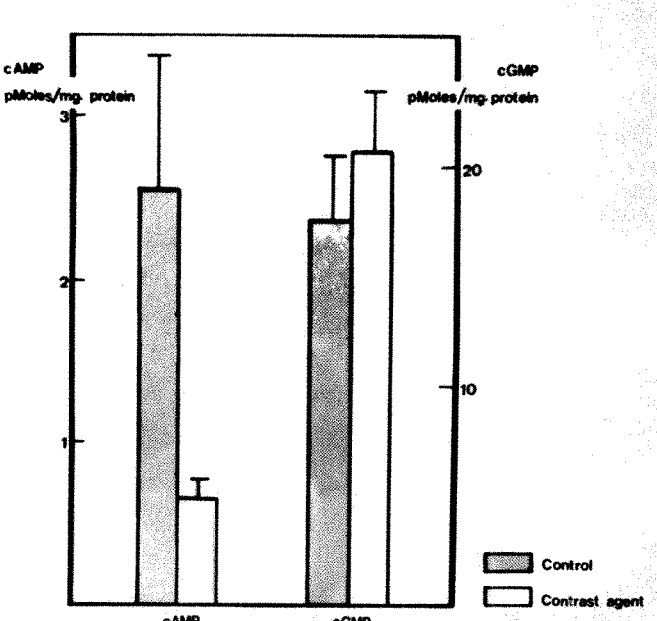

FIGURE 6. Intracellular levels of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) before and after the relaxant effect of contrast agent in a 15% vol/vol dose.

pools of Ca^{2+},[21,22] at least in its earlier phases.[23] However, in a recent report[24] the dog coronary artery was found to be more dependent on extracellular Ca^{2+} than other arteries.

The release of norepinephrine by exocytosis does not seem to play any role in our experimental conditions, because it has been found to be maximal when extracellular K^+ concentration is moderately high (10 to 15 m*M*) and minimal at K^+ concentrations above 20 m*M*.[25]

There is substantial evidence consistent with the hypothesis that cAMP can participate in intracellular processes that lead to coronary smooth muscle relaxation after the administration of beta agonists,[26,27] phosphodiesterase inhibitors,[28,29] adenosine,[30] prostacyclin,[31,32] and several other agents.[33] Böhme,[34] Schultz,[35] and co-workers suggested that cGMP might also be involved in mechanisms leading to a reduction in cytoplasmic Ca^{2+} and thus to smooth muscle relaxation. Available evidence about cGMP and relaxation reveal an interesting association between the intracellular increase of this nucleotide and the smooth muscle relaxation after nitroglycerin,[36] nitroprusside,[37] acetylcholine,[38] and carbachol.[36] Our results which show a significant decrease in cAMP levels in coronary arteries after the relaxation induced by the contrast medium seem to eliminate these nucleotides as the intracellular mediators. However, the preparation used in this study contains more than 1 cell type, and the possibility exists that the changes observed are reflecting changes occurring in nonmuscular cells. It is also possible that the cyclic nucleotides are compartmentalized within the cell and that changes in specific compartments undetected by total tissue measurements are important in the action of the compounds tested in our experiments. Nevertheless, the proposed role of the cyclic nucleotides in the control of the coronary vascular tone emerged from experimental preparations similar to the one we used.

Therefore, until additional evidence is obtained, our results suggest that at least in canine coronary arteries the contrast medium produces relaxation without significantly changing cGMP and despite a decrease in cAMP levels.

With the necessary caution in extrapolating basic research to the clinical setting, some practical information can be inferred from our data. When the effect of a drug on the coronary vascular bed is evaluated by means of angiography, the intrinsic relaxant effect of the angiographic dye should be taken into account. Also, provocative maneuvers frequently used to elicit coronary spasm should be interpreted cautiously, particularly when negative, because this might be attributed to the previous dilatation induced by the contrast agent.

Digital Intravenous Ventriculography: Analysis and Validation of Wall Thickness Changes During Ischemia and Inotropic Stimulation in Dogs

ROBERT A. SLUTSKY, MD, KENNETH H. GERBER, MD, and CHARLES B. HIGGINS, MD,*
with the technical assistance of FRANK H. HAIGLER and FRED G. WERNER

To assess regional ventricular wall thickening, we studied 8 open-chest dogs using digital intravenous ventriculography at a control stage, after subtotal and total coronary occlusion, and then after isoproterenol administration. In 3 dogs, 2 pairs of myocardial thickness crystals were implanted. Correlations of measures of wall thickness and percentage of wall thickening with crystal measures were excellent at the base ($r \geq 0.97$) and near the apex ($r \geq 0.97$). Four areas of the inferoapical wall muscle were measured: the base, mid-wall, distal wall, and apex. Four chamber dimensions were also examined: the long axis, base, mid-wall, and distal wall. End-diastolic thickness decreased with ischemia. At completion occlusion, it was $-24.6 \pm 6\%$ at the base, $-27.3 \pm 5\%$ at the mid-wall, $-27.1 \pm 5\%$ at the distal wall, and $-24.7 \pm 5\%$ at the apex. Percent thickening decreased with occlusion, although greater at the base and mid-wall than at the distal wall and apex. With isoproterenol, end-diastolic thickness increased only at the apex, with little change at the base, distal wall, and mid-wall. Percent thickening increased. In general, ischemia produced increases in end-diastolic hemichords with little change in the long axis. Isoproterenol reduced the hemichords, although the long axis did not change.

We conclude that digital intravenous ventriculograms can be used to assess changes in wall thickness with high degrees of accuracy. Asymmetric thickening occurred at rest, with ischemia and with inotropic stimulation, being greatest at the apex and least at the base.

Analysis of left ventricular wall thickness during the cardiac cycle has received considerable attention in both human and animal investigations.[1–14] Although the data vary with the model utilized, the technique applied, and the underlying hemodynamic condition, the normal ventricular free wall thickens from 20 to 50% during systole.[1–4,11] With acute coronary occlusion, end-diastolic wall thickness declines in large part because of changes in ventricle geometry and reductions in coronary blood flow and volume,[6] whereas systolic thinning occurs frequently.[3,4,7,9,12,13]

Application of contrast angiographic techniques to wall thickness analysis has generally been limited by difficulties in imaging the epicardial surface.[9,11] This problem may be due in part to radiographic and filming difficulties, in addition to mixing difficulties involved with direct chamber injections. Using a potentially simple noninvasive technique, digital intravenous ventriculography, we studied 8 open-chest animals during subtotal and total left circumflex coronary occlusion and then after the intravenous administration of isoproterenol. Wall thickness was measured in 4 locations at end-diastole and end-systole, as were 3 hemichords and a long axis. In 3 animals correlations between implanted wall thickness crystals and measured thickness were made in 2 locations at each intervention point.

The results demonstrate that data obtained from central intravenous injections allow the analysis of regional wall thickness and percent thickening with high degrees of accuracy at multiple intervention points. In addition, thickening appears to be progressively greater near the apex than at the base. This relation was preserved in the presence of both ischemia and inotropic stimulation.

Methods

Animal Preparation

The experiments were conducted in 8 mongrel dogs anesthetized with morphine sulfate (5 mg/kg) and pentobarbital sodium (25 mg/kg). They were ventilated at a rate of 16/min using a Harvard positive-pressure respirator. Through a femoral vein an injection catheter (7 NIH) was placed in the inferior vena cava. Through a left thoracotomy an electro-

magnetic flow probe was placed around the left circumflex artery just proximal to a micromanometer arterial occluder. Another catheter was placed into the ascending aorta. In 5 dogs 2 ultrasonic crystals were placed in opposition on the endocardial surface of the left ventricular chamber distal to the occluder, and another pair were placed on a control region of the myocardium in the distribution of the anterior descending artery.

Ultrasonic crystals: To measure wall thickness in 3 dogs, 1 pair of ultrasonic crystals was placed into the myocardium at the base of the left ventricle, distal to the occluder, and 1 pair at the distal (inferior) wall. The subendocardial crystal was held at the top of a small Teflon® tube and advanced to a site close to the endocardium through a tunnel created by an 18 gauge needle. The epicardial crystal was sutured in place at the site where the ultrasonic transit time was shortest betwen the crystals. The crystals in both directions were positioned after the fluoroscopic position of the dog was established and subsequently used for ventricular imaging. The thickness crystals were then positioned, as well as possible, perpendicular to the fluoroscopic x-ray beam. They were positioned perpendicular to the long axis at both the base and the distal wall of the ventricle. These ultrasonic techniques were previously described and validated in this and other institutions.[4,15,16] The ultrasonic dimension gauge system continuously measures transit time between the piezoelectric crystals, and thereby monitors instantaneous left ventricular internal dimension or wall thickness. Along with an electrocardiographic limb lead, the hemodynamic data were continuously recorded on a multichannel (Gould 2400) direct writing recorder. Pressures were obtained from the aorta using a Statham P23db pressure transducer.

Hemodynamic Manipulations

After data from the control state were obtained, subtotal and total left circumflex occlusions were performed. Subtotal occlusions were defined as being present at the onset of mechanical changes (reduced shortening or thickening). At least 30 minutes were allowed to elapse between studies, permitting the animal to return to control state (defined by the pressure recordings as well as the ultrasonic information). This interval also allowed the effects of the contrast material to wane.[17] Finally, isoproterenol (Isuprel®) was administered (0.1 μg/kg/min) and a 4th series of data acquired.

Radiographic Techniques

A C-arm fluoroscopic unit (Philips, 6 inch cesium iodide image intensifier and a Vidicon television monitor) was located in the 10 to 15 left posterior oblique projection, and images obtained at 65 kV and 3 mA. Through the inferior vena cava, contrast medium was administered with a power injector at a rate of 30 ml/s for 1.0 second. In all studies meglumine sodium diatrizoate (Renografin®-76) was utilized.

Both fluoroscopic data and an electrocardiographic signal were stored in real-time on videotape (JVC high performance, 3/4 inch videotape recorder, CR6600U with a signal to noise ratio of 48 db). The data were then replayed and digitized using a commercially available general purpose medical computer and digitizer (MDS A^2, Ann Arbor, Michigan). Gated acquisitions were made at a rate of 60 fields a second (128 × 128 computer matrix).

Ventricular chamber dimensions and thickness measurements: End-diastole and end-systole were defined by an attenuation-time curve as the nadir and peak of the curve, respectively (Fig. 1). These curves were derived from a fixed left ventricular region-of-interest assigned in the 1st acquired frame (immediately after the R-wave trigger). The end-diastolic and end-systolic images were magnified and displayed on clear Kodak emulsion transparencies. Multiple grips were obtained and similarly magnified and displayed. During the study the distance for grid correction was directly measured (the animal's chest was left open in the pericardial cradle throughout the entire study). Measures of ventricular chamber dimensions and muscle thickness were traced (Fig. 2) and were obtained at end-diastole and end-systole after each intervention. Thus, end-diastolic chord length, volume, and muscle thickness could be manually obtained.

From the ultrasonic crystals, wall thickness at end-diastole was defined as occurring just prior to the upstroke of the aortic pressure recording and end-systole by the dichrotic notch.

At each point then the following chamber dimensions were obtained: (1) long axis, (2) base, (3) mid-wall, and (4) distal wall; and the following muscle thicknesses measured: (1) base, (2) apex, (3) distal wall, and (4) mid-wall. These locations were chosen by dividing the long axis equally by 4. The long axis was drawn from the apex to the juxtaposition of the mitral and aortic valves.

Cardiac output was derived from the heart rate × stroke volume. The latter was obtained from the single plane left ventriculogram and the formula of Kasser and Kennedy.[18] In our laboratory the correlation for this calculation and triplicate thermodilution estimates of cardiac output were tested and found to be excellent (n = 24, r = 0.87). In the 3 dogs with implanted thickness crystals, base and distal wall thicknesses were compared with the angiographic values.

Role of contrast medium: Intravenous administration of contrast material is a requisite for imaging the cardiovascular system with computerized tomography and digital subtraction techniques. In addition to defining anatomy, these modalities have been used to derive physiologic data such as (1) calculation of cardiac output, (2) left ventricular wall thickening, and (3) segmental contraction. An important consideration in the physiologic interpretations of these techniques is the potential hemodynamic alterations caused by the intravenous administration of the contrast material. In a previously completed study,[17] we found that the amount of contrast material utilized in the present study will not alter cardiac hemodynamics if sufficient time elapses between studies (15 to 20 minutes).

Digital Image Manipulation

Acquisition: The videotaped fluoroscopic data were digitized off-line onto an image processing computer (MDS A^2). The information was digitized at a rate of 30 frames/s, with

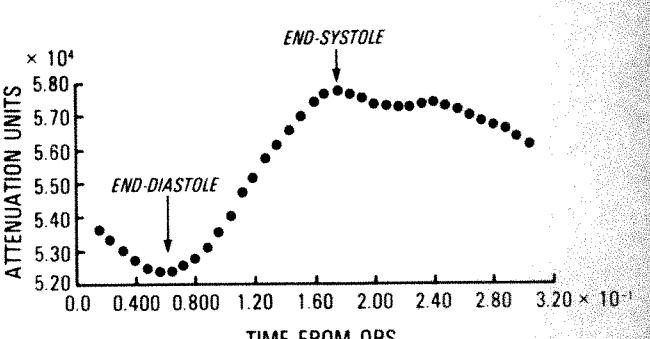

FIGURE 1. Left ventricular time-attenuation curve derived from a fixed, manually assigned left ventricular region-of-interest assigned in the first frame after the peak of the R wave. End-diastole was chosen as the early nadir of the curve and end-systole as the later apex.

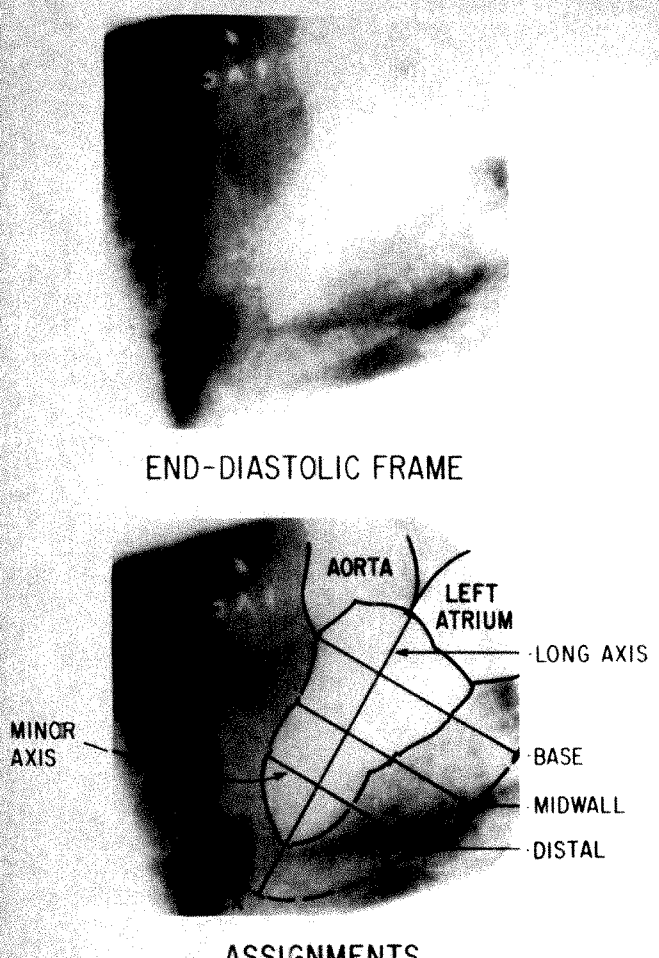

FIGURE 2. Measurements of ventricular chamber dimensions on the digital images and wall thickness. No filtering or subtraction was performed. See text for discussion of the measurements.

2 complete interlaced video fields per frame. The R wave of the electrocardiogram was detected by a physiologic trigger (Picker Cardiac Module) and this signal was used by the computer to initiate acquisition of a single heart beat. Digital acquisition was controlled by the operator to coincide with peak opacification of the left ventricle. Data were recorded in a 128 × 128 matrix with 256 levels of gray. This image matrix yielded a spatial resolution of 1.19 mm/pixel using the 15.24 cm (6 inch) image intensifier.

Image filtering: Temporal frequency filtering was performed on the data as the initial step in improving image quality. Dynamic studies of the cardiovascular system are particularly well suited to this technique. Because the motion of the heart is relatively smooth and undulatory, the individual time-varying frames comprising the study should also be expected to change smoothly and continuously. Stepwise changes occurring from 1 frame to the next are likely attributable to random statistical noise. Rapid changes are characterized by high temporal frequencies; therefore, by frequency filtering in the time domain (temporal frequency filtering), significant improvements in image quality can be obtained because a large amount of medium and high frequency noise can be eliminated while at the same time retaining virtually all of the important low frequencies containing image data. In the present study temporal frequency filtering was performed using a truncated convolution operator to minimize processing time.

Contrast enhancement: Although the data were acquired with 256 levels of gray, not all of these levels corresponded to intensities of interest. For example, regions over the lung fields have minimal x-ray attenuation or maximal x-ray transmission. Because these values were not of interest in the present study, they were displayed with lower gray scale values, and the attenuation values corresponding to the ventricle and its surrounding structures were spread out over the larger portion of the gray scale. This technique for density "windowing" is analogous to the technique used in computerized tomography, wherein only those structures having attenuation values within the operator-selected window are displayed. Both digital radiographic images and computerized tomographic images displayed in this manner allow for discrimination of significantly more subtle degrees of attenuation difference than would be apparent if the data were displayed without windowing.

Statistics: All results are given as the group mean ±1 standard deviation. Differences were tested with a repeated measures analysis of variance for overall significance and the paired t test for individual mean values at various time intervals.[19] Linear correlations were performed using a least-squares linear fit.

Results

Hemodynamics: Cardiac output was 180 ± 60 ml/kg at rest. Stroke volume was 1.76 ± 0.41 ml/kg, heart rate 114 ± 9.4 beats/min, and mean arterial pressure 126 ± 8.5 mm Hg.

With subtotal occlusion induced by a mean reduction in coronary flow of 62.6 ± 4% ($p < 0.01$), cardiac output (170.5 ± 26 ml/kg) declined insignificantly. Arterial pressure declined from the control value (119.0 ± 1.3 versus 126 ± 8.5 mm Hg, $p < 0.05$). With total left circumflex occlusion, mean arterial pressure declined even further (115 ± 12.3 mm Hg, $p < 0.01$ versus control), with a continued although slight decline in cardiac output (169.1 ± 24.9 ml/kg, $p < 0.05$ versus control). Heart rate increased slightly over control values (122 ± 7.9 beats/min, $p < 0.05$), and stroke volume declined (1.37 ± 0.39 ml/kg, $p < 0.05$).

With isoproterenol administration, coronary flow increased (mean increase of 32.8 ± 29.1%, $p < 0.005$ versus control) and mean arterial pressure declined (107 ± 11.3 versus 126.0 ± 8.5 mm Hg at the control data point, $p < 0.01$). Both stroke volume (2.4 ± 0.4 ml/kg, $p < 0.01$) and heart rate (133 ± 11.9 beats/min, $p < 0.01$) were greater than control values.

Thickness correlation data: In 3 dogs, 2 pairs of thickness crystals (1 at the base and 1 at the distal wall) allowed comparisons to be made between the ultrasonic and angiographic methods. Data were obtained at the control state and at all 3 intervention points (subtotal occlusion, total occlusion, and isoproterenol infusion).

The correlation between end-diastolic thickness and percent thickening for the base and distal wall regions was excellent ($r \geq 0.97$) (Fig. 3 and 4). Note that the slope of the thickness measurement at the base is less than the slope from the data at the distal wall. This may be a statistical error, but more likely represents dif-

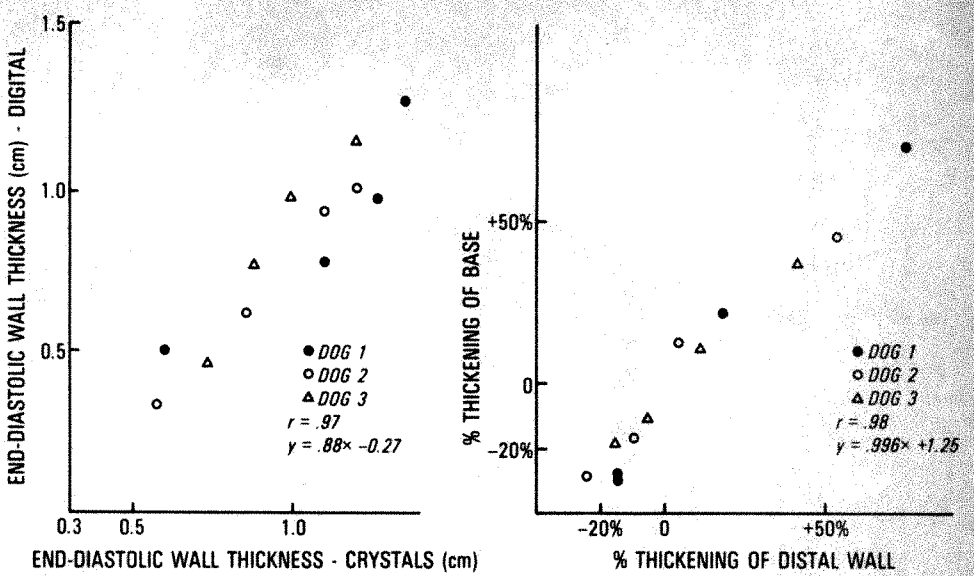

FIGURE 3. Correlations of the percent thickening and end-diastolic wall thickness at the base are given for the digital radiographic (**ordinate**) and sonomicrometer (**abscissa**) techniques.

ficulties with placement of 2 pairs of perfectly parallel sonomicrometers.

End-diastolic thickness and systolic thickening (Fig. 5 and 6): At control level, thickness varied from a mean value of 9.7 ± 1.8 mm at the apex ($p < 0.01$) to 13.4 ± 1.4 mm at the base, 15.6 ± 2.1 mm at the mid-wall, and 14.4 ± 2.1 mm at the distal wall. Mean thickness (average of all 4 locations) was 13.4 ± 2.2 mm. Percent thickening increased as the apex was approached, and was 22.2 ± 13% at the base, 27.6 ± 12.1% at the mid-wall, 43.8 ± 13.0% at the distal wall ($p < 0.05$ versus mid-wall and base), and 61.9 ± 37.3% at the apex ($p < 0.01$ versus base and mid-wall, $p < 0.05$ versus distal wall). The mean percent thickening (average of all 4 locations) was 38.9 ± 17.9%.

Subtotal occlusion induced thinning of the muscle at end-diastole (mean reduction in thickness of 8.4 ± 3.1% versus control, $p < 0.05$). The decline in thickness was 1.5 ± 0.4 mm at the mid-wall, 1.3 + 0.5 mm at the distal wall, and 0.4 ± 0.7 mm at the apex. Percent thickening declined to 5.5 ± 14.7% at the base, 10.4 ± 13.6% at the mid-wall, 29.1 ± 18.3% at the distal wall ($p < 0.05$ versus mid-wall and base) and 68.0 ± 53.0% at the apex ($p < 0.01$ versus mid-wall and base, $p < 0.05$ versus distal wall). Thickening thus appeared to be preserved distally while lost proximally.

With total circumflex occlusion, thinning of the muscle at end-diastole was greater than that at subtotal occlusion. Mean thickness (average of 4 regions) was 9.8 ± 1.8 mm ($p < 0.05$ versus subtotal occlusion value of 12.1 ± 21 mm and $p < 0.01$ versus the control value of 13.3 ± 2.5 mm). The reduction in end-diastolic thickness was similar in all 4 regions (25 ± 6% reduction at the base, 27 ± 4% reduction at the mid-wall, 27 ± 5%

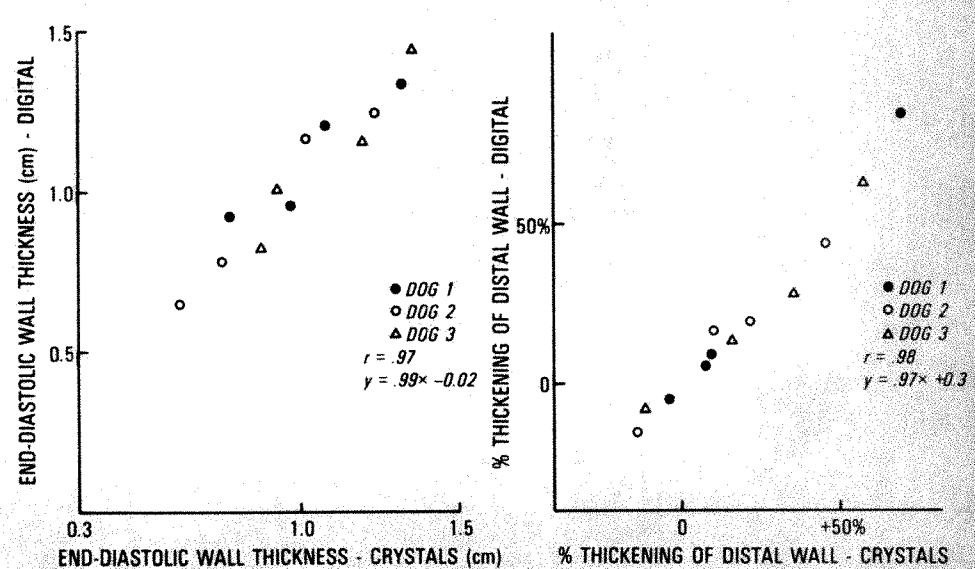

FIGURE 4. Similar to Figure 3 in design. Distal wall thickness correlation data are plotted in the same format as in Figure 3.

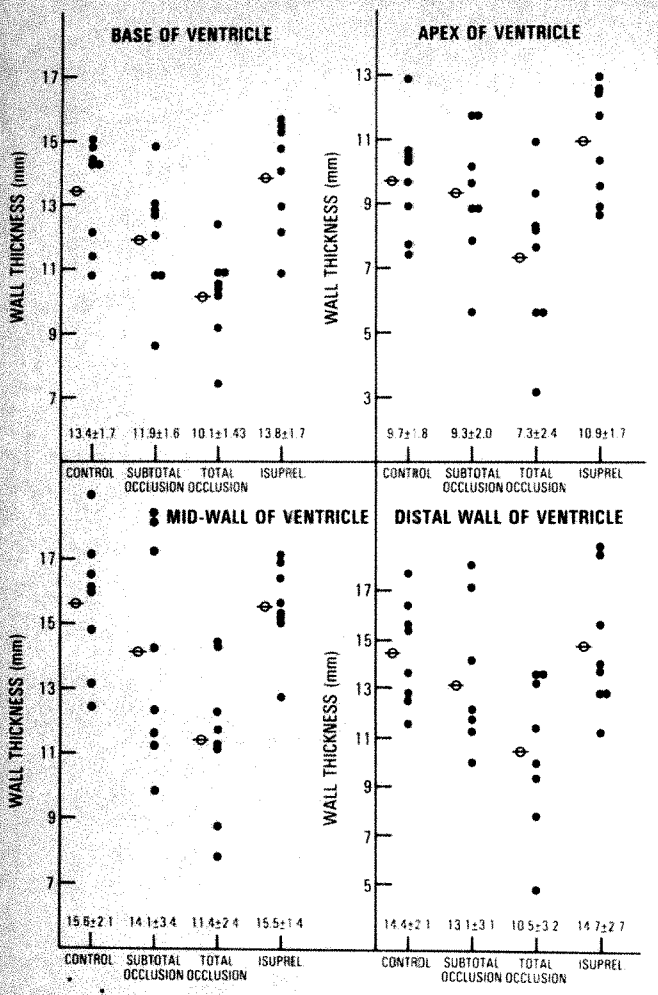

FIGURE 5. End-diastolic wall thickness at each intervention point and at each ventricular region are given. Interventions include subtotal and total coronary occlusion and isoproterenol (ISUPREL).

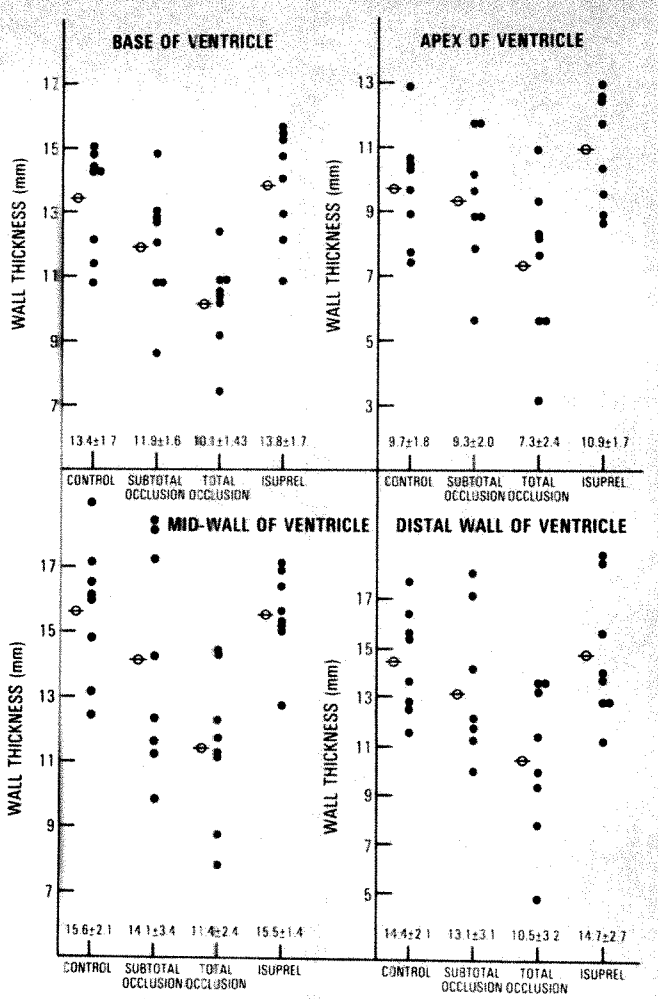

FIGURE 6. Percent wall thickening is given at each region during each intervention in format similar to that in Figure 5.

reduction at the distal wall, and 25 ± 3% at the apex), although the absolute reduction varied with the region analyzed (−3.3 ± 0.7 mm at the base, −4.2 ± 1.1 mm at the mid-wall, −3.9 ± 0.9 mm at the distal wall, and −2.4 ± 0.5 mm at the apex).

Percent thickening followed a similar pattern as seen at the subtotal occlusion intervention point. Thickening tended to be greater distally than near the base. The mean percent thickening was 6.3 ± 10% (average of all 4 regions) and varied from 2.1 ± 27.4% at the distal wall ($p < 0.05$ versus base and mid-wall) and 26.5 ± 30% at the apex ($p < 0.01$ versus base and mid-wall, $p < 0.05$ versus distal wall).

With isoproterenol, the progressive increase in percentage of thickening towards the apex continued to be observed. The mean percent thickening of all 4 regions was 76.8 ± 40.5%, and progressed from 49.1 ± 20.3% at the base, to 60 ± 20.9% at the mid-wall, to 60.9 ± 17.2% at the distal wall, and to 137 ± 35.8% ($p < 0.01$) at the apex. End-diastolic thickness averaged 13.7 ± 2.0 cm (not significantly different from the control value of 13.3 ± 2.5 cm) and was 13.8 ± 1.7 cm at the base, 15.5 ± 1.4 cm at the mid-wall, 14.7 ± 2.7 at the distal wall, and 10.9 ± 1.7 at the apex ($p < 0.05$ versus control value of 9.7 ± 1.8 cm).

Chamber dimensions and systolic shortening (Fig. 7 and 8): In the control state, the long axis was 59.0 ± 8.4 mm compared with 29.0 ± 7.2 mm at the base, 28.0 ± 7.7 mm at the mid-wall, and 23.3 ± 5.4 mm at the distal wall. The ratio of the mid-wall dimension to the long axis was 0.47 ± 0.06. With subtotal and total coronary occlusion, the long axis increased (60.0 ± 9.4 mm and 64.1 ± 14.5 mm, respectively; only the latter different from control, $p < 0.05$). The base widened (from 29.0 ± 72 to 32.3 ± 6.1 to 37.9 ± 8.7 mm, $p < 0.01$ for total occlusion versus control, and $p < 0.05$ versus subtotal occlusion) as did the mid-wall dimension (28.0 ± 7.7, to 30.9 ± 5.3, to 39.5 ± 10.8 mm, $p < 0.01$ for occlusion versus control and subtotal occlusion) and the distal wall dimension (23.3 ± 5.4, to 25.8 ± 4.7, to 33.7 ± 9.5 mm, total occlusion $p < 0.01$ versus control and $p < 0.05$ versus subtotal occlusion). The ratio of the mid-wall dimension to long axis increased (0.47 ± 0.06 at control, to 0.48 ± 0.07 at subtotal occlusion, to 0.62 ± 0.08 at total occlusion; the latter $p < 0.01$ versus control and subtotal occlusion).

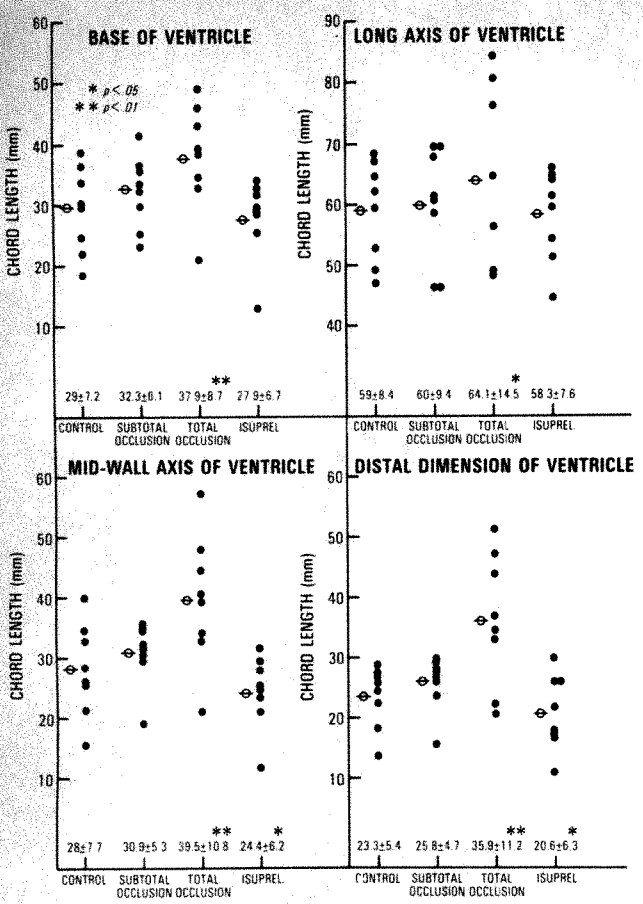

FIGURE 7. Chamber dimensions (long axis and 3 minor chords) are given at each region during each intervention. Format similar to that in Figure 5.

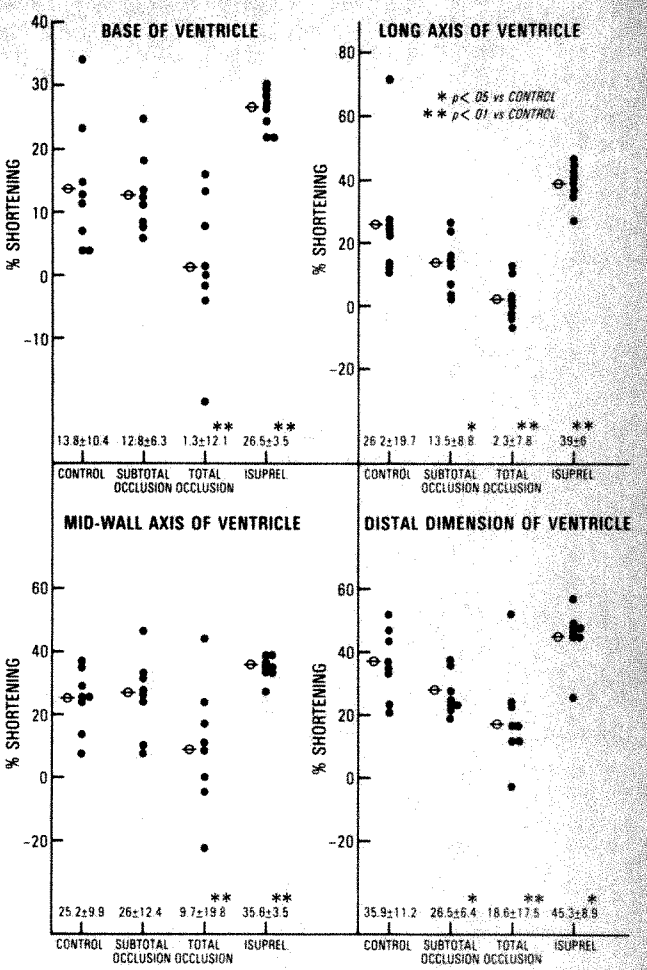

FIGURE 8. Percent dimension (internal chamber dimension) is given at each region during each intervention. Format similar to that in Figure 5.

The percent shortening (%) at the control state was 13.8 ± 10.4 at the base, 25.2 ± 9.9 at the mid-wall, 35.9 ± 11.2 at the distal wall, and 26.2 ± 19.7 at the apex. With subtotal occlusion, few changes in chamber shortening occurred. With total occlusion, all regions shortened less (1.3 ± 12.1% at the base, $p < 0.01$ versus control; 9.7 ± 19.8% at the mid-wall, $p < 0.01$ versus control; 18.6 ± 17.5% at the distal wall, $p < 0.01$ versus control; and 2.3 ± 7.8% at the apex, $p < 0.01$ versus control). Note that shortening was greater at the distal wall than at the base, and that this finding persisted with ischemic interventions.

Isoproterenol produced increases in shortening, again with the base shortening less than the distal wall (26.5 ± 3.1% at the base, 35.6 ± 3.5% at the mid-wall, 45.3 ± 8.9% at the distal wall, and 39 ± 6% at the long axis; all $p < 0.01$ versus control values). Neither the long axis nor the base dimension was different from the respective control values (58.3 ± 7.6 versus 59.0 ± 8.4 mm and 27.9 ± 6.7 versus 39.0 ± 72 mm). However, the mid-wall and distal wall dimensions were significantly smaller (24.4 ± 6.2 versus 30.9 ± 5.3 mm, $p < 0.05$, respectively). The ratio of the mid-wall dimension to the long axis decreased (0.41 ± 0.008, $p < 0.05$ versus control and subtotal occlusion and $p < 0.01$ versus total occlusion).

Discussion

Methodologic considerations: As in previous studies, we found that myocardial thickening in the basal state varies from 20 to 50%. Previous studies using contrast ventriculography to identify the myocardial wall have proved difficult, particularly when left ventricular hypertrophy was present.[11] Our data in open-chest dogs suggest that digital ventriculography may be a feasible technique for estimating wall thickness and percent thickening. Unlike in previous studies,[10,11] contrast medium was injected into the inferior vena cava, thus permitting excellent mixing with the blood pool. Additionally, lower transmission x-ray energy maximized attenuation differences between the contrast-containing blood in the chamber, the myocardial muscle (with less blood), and the lung. However, our study involved open-chest animals, with images performed at held inhalation. Moreover, none of the animals had left ventricular hypertrophy, although with isoproterenol infusion the end-systolic thickness approximated this condition. It might be pointed out that the isoproterenol correlation data appeared identical to the control and ischemia data.

Rotation during systole was neither measured nor corrected for; nonetheless, in this projection it did not appear to influence the results or correlations. Importantly, the inferoposterior wall was chosen because it did not overlap with the right ventricular chamber and wall in this projection. The anterolateral wall (in the traditional more shallow right anterior oblique view) may conceivably be more prone to rotational distortion. Alteration of the geometric configuration of the muscle at end-systole in the right anterior oblique view might result in alterations in the anatomic configuration of the ventricular muscle tangential to the x-ray beam, and could produce inaccurate overestimations of wall thickness and percent thickening. In 4 dogs, tantalum markers were sutured to the apex (apical dimple) and to the area near the aortic and mitral valve (appendage). The rotation of the line connecting these 2 points was less than 10%. Nonetheless, rotation out of the unidimensional plane could not be corrected for and must remain a significant problem and limitation of the method.

Effect of ischemia on systolic ventricular wall thickening: In the "basal" (open-chest, morphine-pentobarbital anesthesia, held inhalation) state, systolic thickening appeared greater towards the apex and less towards the base. With ischemia (total and subtotal occlusion), these relations were maintained. It is difficult to know whether the distal wall and apex received more collateral flow, thus permitting contraction. It did appear that the decline in thickening was similar in all regions, but the apex and distal wall started at greater absolute percent thickening. Isoproterenol provoked increases in percent thickening in a pattern similar to the rest and ischemia data. Of note was the fact that end-diastolic thickness was only greater at the apex after flow was increased. Ischemia produced gradual decreases in end-diastolic thickness. The latter findings are in all likelihood due to the reduction in coronary flow and the change in ventricular chamber geometry. With ischemia (particularly in total occlusion), the ventricular chamber assumes a more spherical configuration; that is, the ratio of the mid-wall dimension/long axis more closely approaches unity. This might result in end-diastolic thinning. Nonetheless, Gaasch and Bernard[6] showed the thinning effects of ischemia on the end-diastolic muscle dimension. They also demonstrated that with reperfusion hyperemia and coronary papaverine and nitroglycerin injections, increases in coronary flow produced increases in end-diastolic wall thickness. The flow changes in their experiments were substantially greater than those in our studies. We were unable to accurately assess ischemic reperfusion because of the limited number of contrast injections that could be performed without producing hemodynamic changes, and isoproterenol only increased flow by approximately 30%.

Similar to other investigators using a variety of other techniques,[3,4,6-9] we found that ischemia reduced percent thickening and end-diastolic thickness. Occasionally, end-systolic thinning occurred, particularly at the base and mid-wall. Chamber dimensions increased with ischemia, and percent shortening declined. These changes corresponded to an increase in end-diastolic volume and a decline in cardiac output and stroke volume.

Implications: We conclude that digital intravenous ventriculography is a useful technique for the evaluation of myocardial wall thickness and chamber geometry in dogs. Measurements of wall dimensions correlate well with standard sonomicrometer measures, and changes in 1 technique agree well with changes in the other. Whether this technique is feasible in man, when the chest is closed, the anteroposterior diameter is greater, and the administered contrast medium doses are lower, will require extensive further investigation.

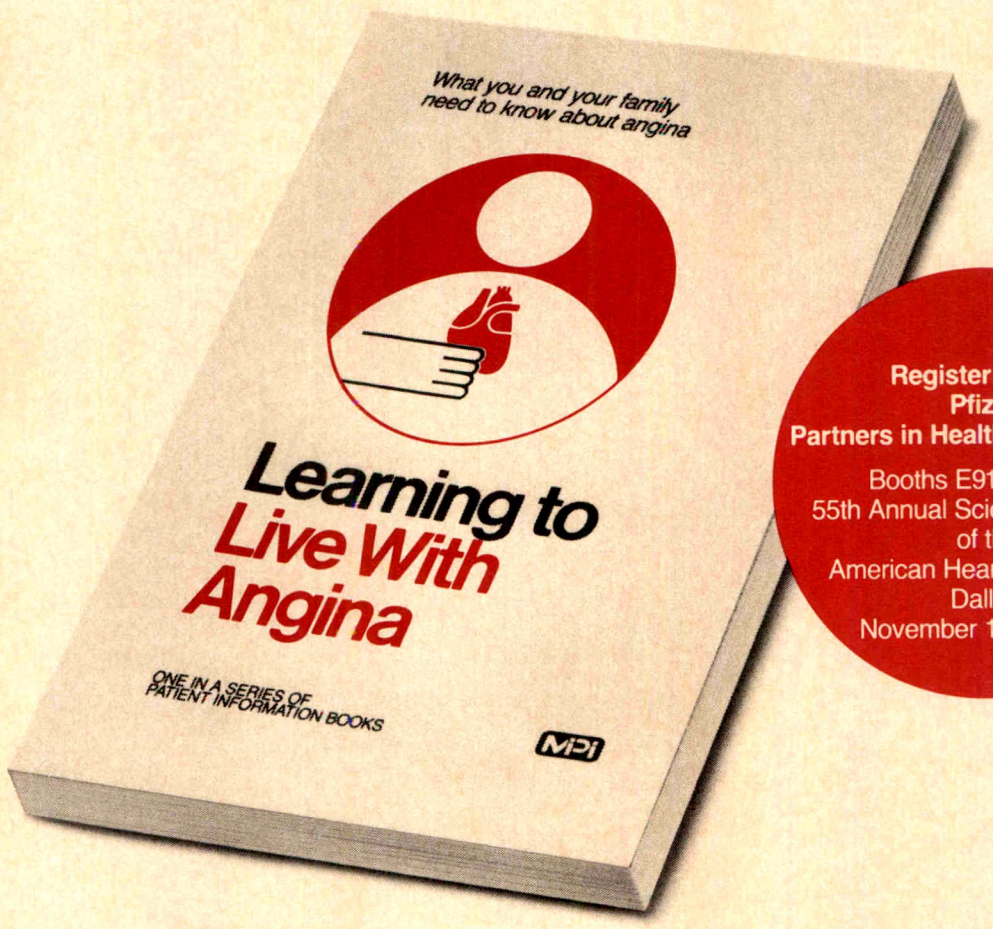
THE MOST COMPREHENSIVE PATIENT INFORMATION BOOK ON ANGINA TODAY



Register for the Pfizer Partners in Healthcare Program.

Booths E91 and E93,
55th Annual Scientific Sessions
of the
American Heart Association,
Dallas,
November 15-18, 1982.

Learning to Live With Angina—A unique 75-page patient information book: Clear, comprehensive, designed to improve patient compliance.

A book compiled by outstanding physicians from major medical centers with extensive experience in communicating patient information, *Learning to Live With Angina* is a highly readable, comprehensive work that helps your patients comply more fully with your treatment regimen. Used *under your direction,* it becomes a valuable aid in the adjustment of a patient to his illness.

Pfizer

Learning to Live With Angina.
Valuable information for patient compliance.
Distributed as a public service by Pfizer.

NOW...FOR OPTIMAL HEMODYNAMIC RESPONSE
(nitroglycerin) TRIDIL®
THE IV NITRO
Tridil™
Tridil™
Tridil™
10 ml
Tridil™
© 1982 American Critical Care
Division of American Hospital Supply Corporation
Tridil is a concentrated
drug which must be
diluted prior to use.

IN CHF ASSOCIATED WITH ACUTE MI

SYSTEM THAT DELIVERS

Efficacy:

- Quickly relieves pulmonary congestion with little effect on cardiac output[1]
- Helps redistribute blood flow to the infarcted myocardium[2,3]

Predictability:

- Produces dose-responsive venous and arterial dilation to help control both preload and afterload
- Tridilset,™ a special non-absorbing IV administration set, delivers Tridil with the greatest possible accuracy[4,5]

Safety:

- Metabolites have only minor activity and are rapidly excreted
- Highly concentrated Tridil (5 mg/ml) helps avoid the risk of fluid overload (especially helpful in the presence of oliguria)

***TRIDIL SYSTEM*—the preferred IV nitroglycerin in CHF associated with acute MI**

- Highest concentration currently available—easy dilution, convenient administration, conserves fluid intake.
- Non-absorbing Tridilset IV set allows precise titration
- Comprehensive clinical/technical support

TRIDIL SYSTEM

delivers a new level of therapeutic precision to the treatment of CHF associated with acute MI

Please see the following page for a brief summary of prescribing information.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinylchloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,™ an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

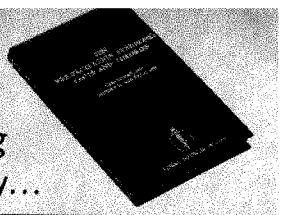
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal*. Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as Methods, Results, and Comments. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96:766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

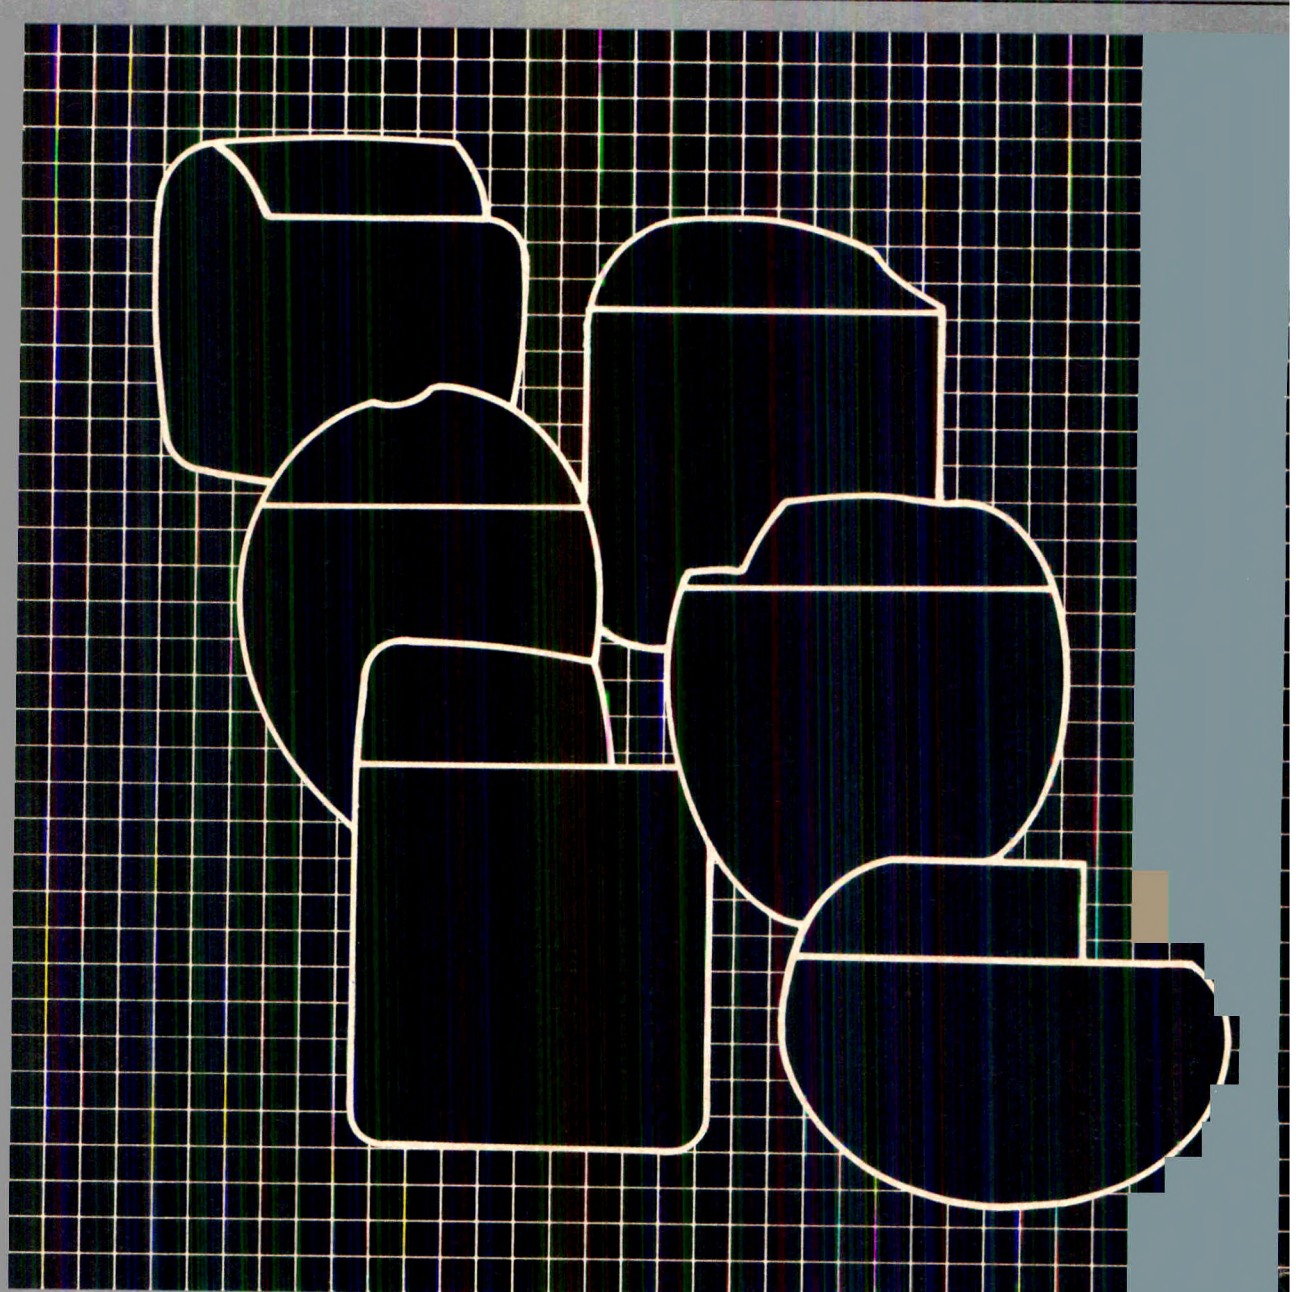
> **Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.
>
> **Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.
>
> **Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

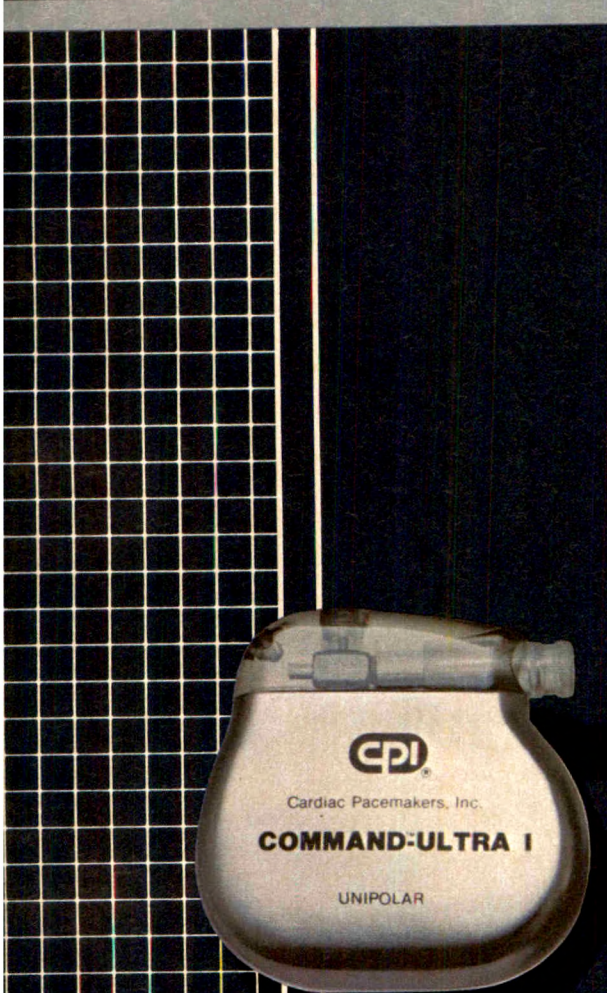
TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

CPI® ULTRA I INVITES COMPARISON WITH ANY PACING SYSTEM



- Ultra I has complete multiprogrammability—rate, pulse width, sensitivity, hysteresis, pulse amplitude, refractory period, mode.
- Ultra I will have a printout to document all programming and memory information.
- Contact your CPI representative for a demonstration.
- Or call toll free (800) 328-9588.



The only pacemaker with MEMORY for pulse generator, lead and patient data. Ultra I memory banks store patient pacemaker history.

The only pacemaker that MONITORS patient pacemaker dependency.

The only pacemaker with total information retrieval via TELEMETRY with a handheld programmer.

The only pacemaker that can telemeter paced and sensed events via a DIAGNOSTIC intracardiac electrogram.

CPI

Energy for Life

Ativan®: Agent
(lorazepam)

because...

it's shorter acting, with brief accumulation

In contrast to long-acting benzodiazepines, Ativan has a short, 12-hour half-life, and no active metabolites. In multiple-dose therapy, Ativan accumulates for only 2 to 3 days before reaching steady state; the long-acting benzodiazepines—diazepam CIV, chlordiazepoxide CIV, clorazepate CIV and prazepam CIV—with their active metabolites accumulate for as long as 20 days before reaching steady state. Cumulative sedative effects are seldom a problem with Ativan.[1]

it doesn't interact with drug metabolized by P450 microsomal enzyme

Most benzodiazepines undergo oxidative metabolis and thus utilize the hepatic microsomal enzyme system. Ativan® (lorazepam), however, is metabolize by glucuronidation and does not compete with other drugs for cytochrome P450. Thus, when Ativa is given with Tagamet® (cimetidine), for example, clearance is not delayed, nor sedation increased*—unlike reported observations with patients on othe benzodiazepines.[2-6]

*All benzodiazepines produce additive effects when given with CNS depressants such as barbiturates or alcohol.

Copyright © 1982, Wyeth Laboratories. All rights reserved.

# of Change

t gives you greater control of therapy

he short half-life of Ativan® (lorazepam) facilitates nore rapid response to dosage adjustments, llowing you to titrate therapy to patients' changing eeds. Also, once you decide to discontinue Ativan, will be out of your patient's system 4 days after the nal dose—in contrast to long-acting benzodiazepines nd their active metabolites which take as much as weeks to be totally eliminated.

Ativan®
for (lorazepam)℞ Anxiety

Wyeth Laboratories
Philadelphia, PA 19101

See important information on following page.

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan®
for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

What is CARDIOLOGY 1982

- The second in an annual series to be published SPRING each year
- A review of the year's newest and most import developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and app research based on an exhaustive search of the literature
- A unique, cohesive summary of the state-of-th written, not edited, by those making outstandi developments in the field
- A practical approach to a complicated and fast subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhe

"It is more than merely a reference book, since it explains average physician may be obscure....a treasure house of 19 publications. It is highly recommended." Philip Reichert, M.D New York State Jour Medicine, Septembe

"...recommend...to any reader interested in the literature o cardiology." Irwin R. Callen, M.D JAMA, November, 1

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions

☐ **YES,** please enter my sta order for CARDIOLOGY: 1982 derstand that each edition (pub once a year) will be automa shipped to me on 30 day approva I will receive a 10% discount c and all future editions. (1982 discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, NY 11205

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish standing order.

☐ Enclosed is my check for ..... Yorke pays postage and handling. (Same return privilege)

(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Cana

☐ Please bill my ☐ VISA ☐ MasterCard (same return privilege)

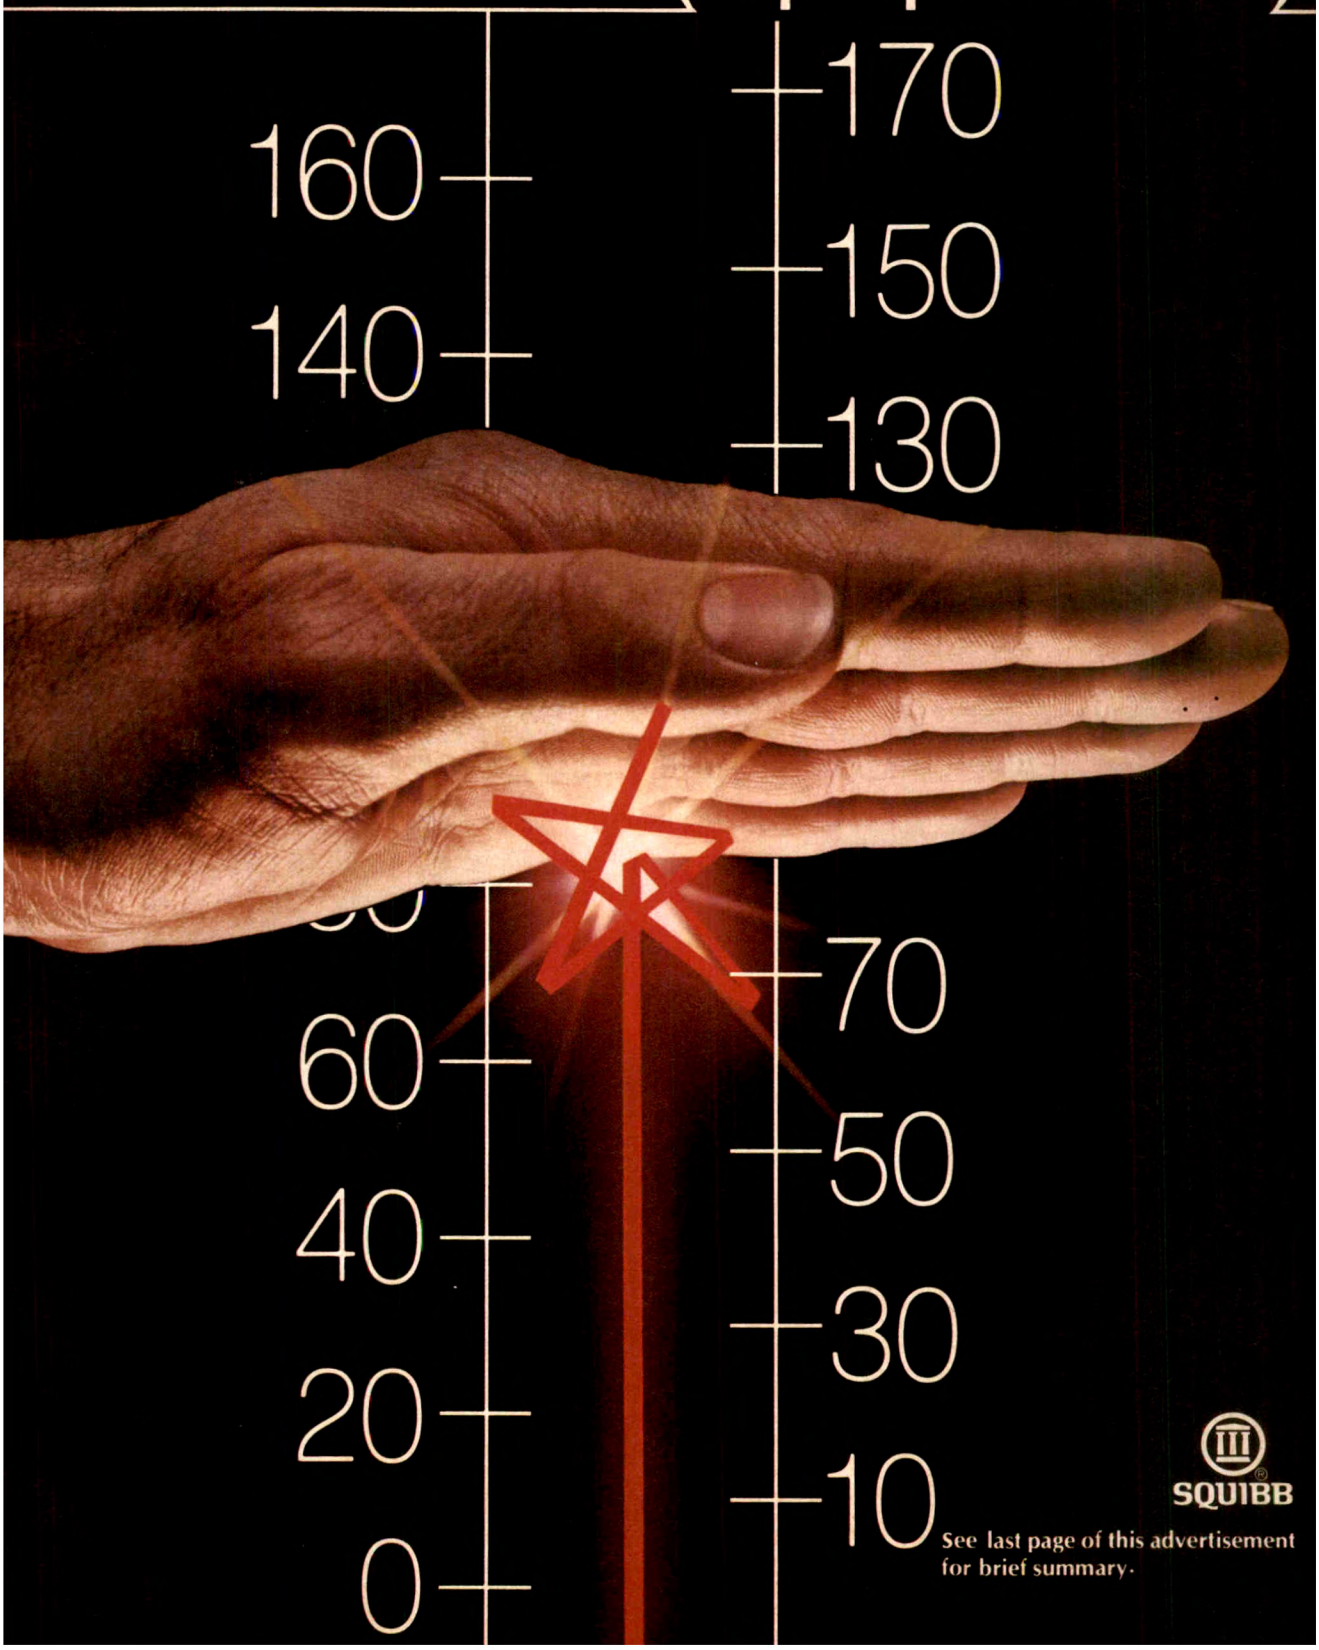
Designed to achieve your therapeutic goals in hypertension

CAPOTEN® (captopril tablets)



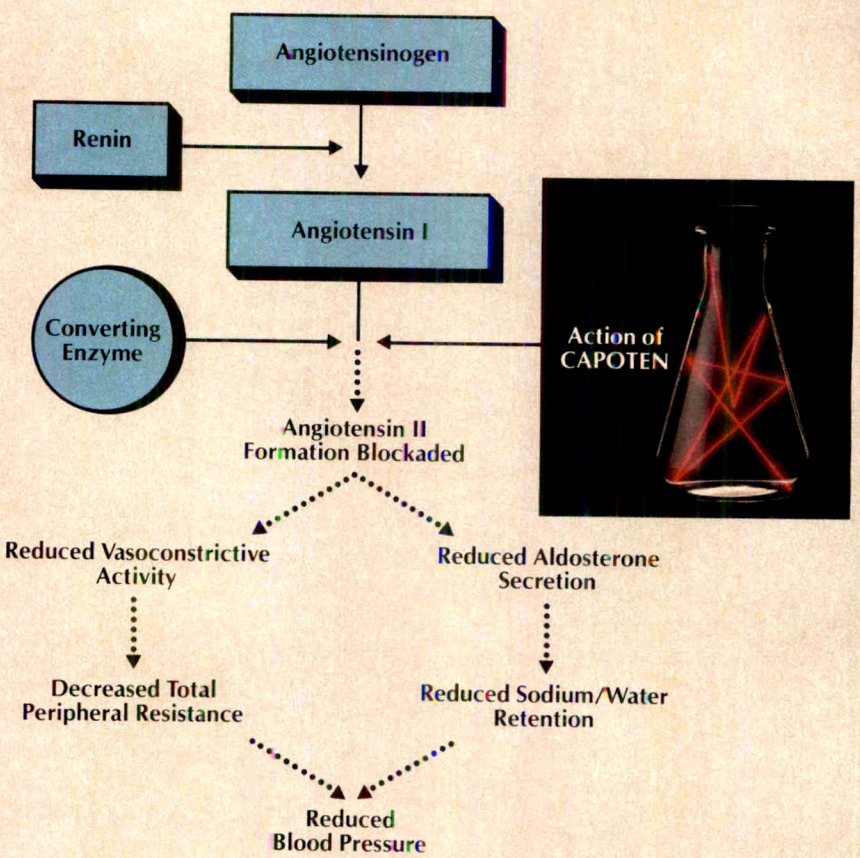
SQUIBB

See last page of this advertisement for brief summary.

ACE* INHIBITOR

CAPOTEN® (captopril tablets)

Because of its specific action within the renin-angiotensin-aldosterone (RAA) system, CAPOTEN enables you to reliably control blood pressure in a diverse group of hypertensive patients.



For hypertensive patients:

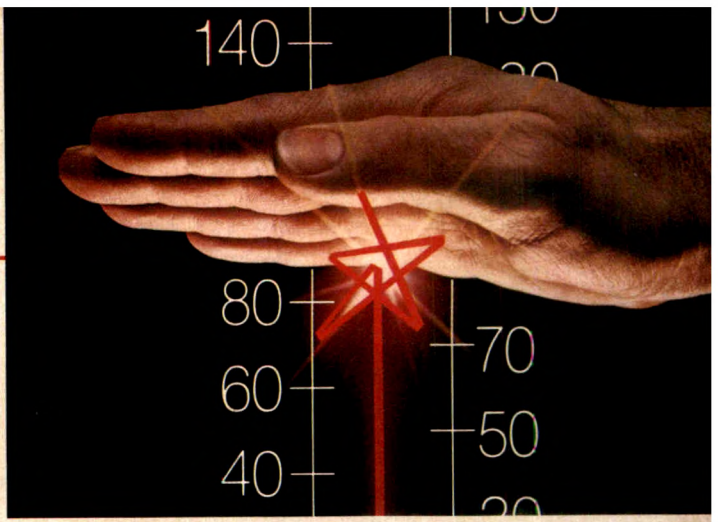
who experience unacceptable side effects with beta blockers, antiadrenergic agents, or vasodilators

whose blood pressure is uncontrolled by standard multidrug regimens

who have concomitant conditions contraindicating use of other antihypertensive agents

*Angiotensin Converting Enzyme

SQUIBB



A design that controls blood pressure without the following usual antihypertensive side effects*

- ▶ No cardiac depression
- ▶ No glucose intolerance
- ▶ No bradycardia
- ▶ No mental depression
- ▶ No sleep disturbances
- ▶ No nasal congestion
- ▶ No hypokalemia

- ▶ Rare impotence/loss of libido
- ▶ Rare bronchospasm
- ▶ Rare tachycardia
- ▶ Rare fatigue

ACE INHIBITOR

CAPOTEN®
(captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

ACE* INHIBITOR

CAPOTEN® (captopril tablets)

Designed to control blood pressure even when coexisting disorders complicate hypertension management

Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- **Bronchospastic disease**
- **Cardiac arrhythmias**
- **Congestive heart failure**
- **Diabetes mellitus**
- **Hepatic disease**

Designed to control blood pressure when conventional multidrug regimens have proven inadequate

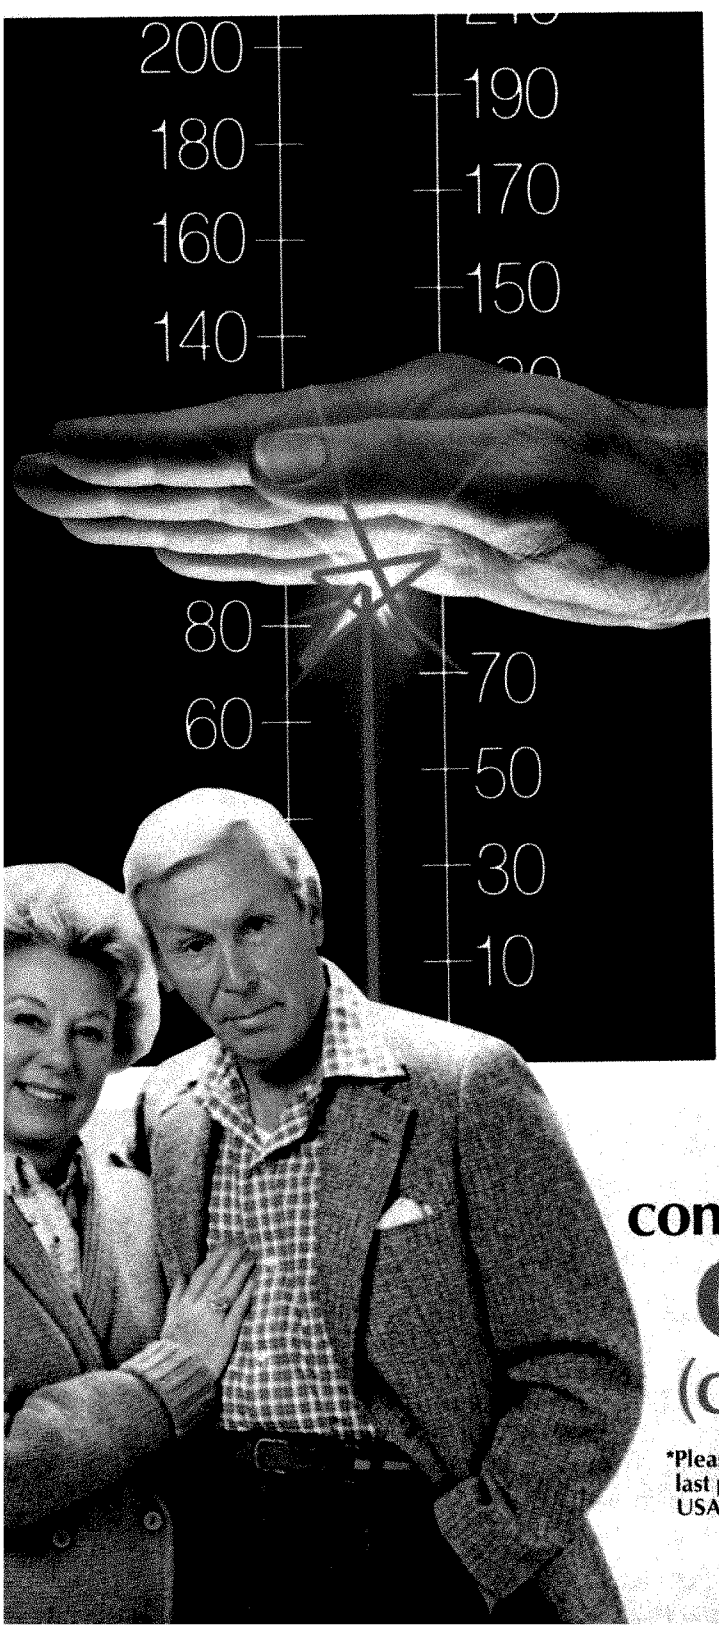
In scores of clinical studies, the effectiveness of CAPOTEN in lowering elevated blood pressure has been proven in many kinds of hypertension—even in those types that are most difficult to treat.

- **Essential hypertension**
- **Hypertension resistant to standard triple therapy (STT)**
- **Hypertension associated with low, normal, and high plasma renin levels**
- **Renovascular hypertension**

*Angiotensin Converting Enzyme

Designed to achieve your therapeutic goals in hypertension

SQUIBB



Effective blood pressure control

▶ Routine monitoring procedures are recommended because serious side effects (neutropenia/agranulocytosis, proteinuria) have been associated with CAPOTEN.*

▶ Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.

▶ Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.

▶ Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.

▶ The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.

In hypertension... confidence comes with

CAPOTEN®

(captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

Captopril Tablets

DESCRIPTION: Capoten (captopril) is a specific competitive inhibitor of angiotensin I-converting enzyme (ACE), the enzyme responsible for converting angiotensin I to angiotensin II.

INDICATIONS: Because serious adverse effects have been reported (see WARNINGS), Capoten is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects. Usually, multidrug regimens include combinations of a diuretic, a sympathetic nervous system-active agent (such as a beta-blocker) and a vasodilator.

Capoten (captopril) is effective alone, but in the population described above, it should usually be used in combination with a thiazide-type diuretic. The blood pressure lowering effects of captopril and thiazides appear to be additive.

WARNINGS: Proteinuria—Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. Existence of prior renal disease increased the likelihood of development of proteinuria. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued, but some patients had persistent proteinuria. The BUN and creatinine were seldom altered in the proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related; this is uncertain since patients were not biopsied prior to treatment and membranous glomerulopathy may be associated with hypertension in absence of captopril therapy. Since most cases of proteinuria occurred by the 8th month of captopril therapy, patients on captopril should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine—the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis—Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller, and it is sufficient in these patients to have white blood cell counts every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension—Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in severely salt/volume depleted persons such as those treated vigorously with diuretics, e.g., patients with severe congestive heart failure (see PRECAUTIONS [Drug Interactions]).

PRECAUTIONS: General: *Impaired Renal Function*—Some patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine after reduction of blood pressure with captopril. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible (see DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]). *Surgery/Anesthesia*—During major surgery or anesthesia with agents that produce hypotension, captopril will block angiotensin II formation secondary to compensatory renin release; if hypotension occurs and is considered due to this mechanism, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy*—A precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretic therapy and those on severe dietary salt restriction or dialysis. The possibility of hypotensive effects can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose. If hypotension occurs, place the patient in a supine position and, if necessary, administer an I.V. infusion of normal saline. This transient hypotensive response is not a contraindication to further doses which can be given without difficulty once the blood pressure has increased after volume expansion.

Agents Causing Renin Release—Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity—The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium—Since captopril decreases aldosterone production, elevation of serum potassium may occur. Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. If the patient has received spironolactone at any time up to several months prior to captopril therapy, determine the serum potassium frequently since the effect of spironolactone persists.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential.

Animal Toxicology: Chronic oral toxicity studies were conducted in rats (2 years), dogs (47 weeks; 1 year), mice (2 years), and monkeys (1 year). Significant drug-related toxicity included effects on hematopoiesis, renal toxicity, erosion/ulceration of the stomach, and variation of retinal blood vessels. Reductions in hemoglobin and/or hematocrit values were seen in mice, rats, and monkeys at doses 50 to 150 times the maximum recommended human dose (MRHD). Anemia, leukopenia, thrombocytopenia, and bone marrow suppression occurred in dogs at doses 8 to 30 times MRHD. The reductions in hemoglobin and hematocrit values in rats and mice were only significant at 1 year and returned to normal with continued dosing by the end of the study. Marked anemia was seen at all dose levels (8 to 30 times MRHD) in dogs, whereas moderate to marked leukopenia was noted only at 15 and 30 times MRHD and thrombocytopenia at 30 times MRHD. The anemia could be reversed upon discontinuation of dosing. Bone marrow suppression occurred to a varying degree, being associated only with dogs that died or were sacri-

[illegible] in a moribund condition in the 1 year study. However, in the 47-week study at a 30 times MRHD, bone marrow suppression was found to be reversible upon conti drug administration. Captopril caused hyperplasia of the juxtaglomerular apparatus c kidneys at doses 7 to 200 times the MRHD in rats and mice, at 20 to 60 times M in monkeys, and at 30 times the MRHD in dogs. Gastric erosions/ulcerations wer creased in incidence at 20 and 200 times MRHD in male rats and at 30 and 65 times M in dogs and monkeys, respectively. Rabbits developed gastric and intestinal ulcers given oral doses about 30 times MRHD for only 5 to 7 days. In the two-year rat study, versible and progressive variations in the caliber of retinal vessels (focal saccula and constrictions) occurred at all dose levels (7 to 200 times MRHD) in a dose-re fashion. The effect was first observed in the 88th week of dosing, with a progress increased incidence thereafter, even after cessation of dosing.

Pregnancy: Category C—Captopril was embryocidal in rabbits when given in doses 2 t times (on a mg/kg basis) the maximum recommended human dose. The marked bryocidal effect in rabbits was most probably due to the particularly marked decr in blood pressure caused by the drug in this species. Captopril given to pregnant ra 400 times the recommended human dose continuously during gestation and lacta reduced neonatal survival. No teratogenic effects (malformations) have been seen large doses of captopril in hamsters, rats, and rabbits.

There are no adequate and well-controlled studies in pregnant women. Capt should be used during pregnancy only if the potential benefit justifies the potential to the fetus.

Nursing Mothers: Concentrations of captopril in human milk are about 1% of thos maternal blood. The effect of low levels of captopril on the nursing infant has not b determined. Exercise caution when administering captopril to a nursing woman, an general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established altho there is limited experience with use of captopril in children from 2 months to 15 y of age with secondary hypertension and varying degrees of renal insufficiency. Dos on a weight basis, was comparable to that used in adults. Captopril should be use children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving a 4000 patients.

Renal—One to 2 of 100 patients developed proteinuria (see WARNINGS). Rena sufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 pati but relationship to drug use is uncertain.

Hematologic—Neutropenia/agranulocytosis (probably drug related) occurred in al 0.3% of captopril treated patients (see WARNINGS). Two of these patients develc sepsis and died.

Dermatologic—Rash (usually maculopapular, rarely urticarial), often with pruritus sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 4 weeks of therapy. The rash is usually mild and disappears within a few days of dos reduction, short-term treatment with an antihistaminic agent, and/or discontinuing t apy; remission may occur even if captopril is continued. Pruritus, without rash, in al 2 of 100 patients. Between 7 and 10% of patients with skin rash have shown an eos philia and/or positive ANA titers. A reversible associated pemphigoid-like lesion, photosensitivity have also been reported. Angioedema of the face, mucous membra of the mouth, or of the extremities in about 1 of 100 patients—reversible on discon ance of captopril therapy. One case of laryngeal edema reported. Flushing or pallc 2 to 5 of 1000 patients.

Cardiovascular—Hypotension in about 2 of 100 patients. See PRECAUTIONS (D Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycar chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocar infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1 patients.

Dysgeusia—About 7 of 100 patients developed a diminution or loss of taste per tion; taste impairment is reversible and usually self-limited even with continued drug (2 to 3 months). Weight loss may be associated with the loss of taste. Gastric irritat abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulc peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, paresthesias reported in about 0.5 to 2% of patients but did not appear at increa frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although causal relationship has been established. A single case of hepatocellular injury secondary cholestasis has been reported in association with captopril use. A trans elevation of BUN and serum creatinine may occur, especially in volume-depleted or re vascular hypertensive patients. In instances of rapid reduction of longstanding or seve elevated blood pressure, the glomerular filtration rate may decrease transiently, resulting in transient rises in serum creatinine and BUN. Small increases in serum po sium concentration frequently occur, especially in patients with renal impairment (PRECAUTIONS).

OVERDOSAGE: Primary concern is correction of hypotension. Volume expansion with I.V. infusion of normal saline is the treatment of choice for restoration of blood p sure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour bef meals. Dosage must be individualized.

Give consideration to recent antihypertensive drug therapy, extent of blood press elevation, salt restriction, and other circumstances before initiating therapy. If possi discontinue the patient's previous antihypertensive drug regimen for one week bef starting captopril. Initial dose of CAPOTEN (captopril) is 25 mg t.i.d. If satisfactory bl pressure reduction is not achieved after 1 or 2 weeks, dose may be increased to 50 t.i.d. If the blood pressure has not been satisfactorily controlled after another 1 to 2 wee add a modest dose of a thiazide-type diuretic (e.g., hydrochlorothiazide, 25 mg dai The diuretic dose may be increased at 1- to 2-week intervals until its highest usual a hypertensive dose is reached. If further blood pressure reduction is required, CAPOT (captopril) may be increased to 100 mg t.i.d. and then, if necessary, to 150 mg t. (while continuing the diuretic). The usual dose range is 25 to 150 mg t.i.d. A maxim daily dose of 450 mg CAPOTEN (captopril) should not be exceeded.

For patients with accelerated or malignant hypertension, when temporary discontin tion of current antihypertensive therapy is not practical, or when prompt titration to m normotensive blood pressure levels is indicated, current antihypertensive medication n be stopped and CAPOTEN (captopril) dosage promptly initiated at 25 mg t.i.d., under cl medical supervision. The daily dose of CAPOTEN (captopril) may be increased every hours until a satisfactory blood pressure response is obtained or the maximum capto dose is reached. In this regimen, addition of a more potent diuretic, e.g., furosemi may also be indicated. Beta-blockers may also be used in conjunction with capto therapy (see PRECAUTIONS [Drug Interactions]), but the effects of the 2 drugs are l than additive.

Dosage Adjustment in Renal Impairment—Because CAPOTEN (captopril) is excret primarily by the kidneys, excretion rates are reduced in patients with impaired renal fu tion. These patients will take longer to reach steady-state captopril levels and will rea higher steady-state captopril levels for a given daily dose than patients with normal re function. Therefore, these patients may respond to smaller or less frequent doses. cordingly, for patients with significant renal impairment, initial daily dosage of CAPOT (captopril) should be reduced, and smaller increments utilized for titration, which sho be quite slow (1- to 2-week intervals). After desired therapeutic effect has been achiev dose should be slowly back-titrated to determine minimal effective dose. When c comitant diuretic therapy is required, a loop diuretic (e.g., furosemide), rather thar thiazide diuretic, is preferred in patients with severe renal impairment.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and UNIMATIC® unit-dose packs of 100 tablets.

KLOTRIX®
(POTASSIUM CHLORIDE) SLOW-RELEASE TABLETS, 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS—BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.

Note: KLOTRIX® slow-release tablets must be swallowed whole and never crushed or chewed. Following release of the potassium chloride, the expended wax matrix, which is not absorbed, may be observed in the stool.

HOW SUPPLIED Bottles of 100, 1000, and Unit Dose cartons of 100.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES II CORONARY DISEASE

The most up-to-date referen on the state of the art of medical and surgical myoc dial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularizati features the latest on:

- Streptokinase - Thrombolysis in A (Percutaneous Transluminal Coro Recanalization (PTCR)
- Percutaneous Transluminal Coror Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Anç Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205

CHANGING ANGINA THERAPY

Calan™
(verapamil HCl)
TABLETS
80 mg and 120 mg

The Prototype Calcium Antagonist

Please see the following page for a brief summary of the complete prescribing information.

Calan™ TABLETS 80 mg and 120 mg
(verapamil HCl)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure < 90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction < 30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR < 50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

$19.50 softbound
ISBN 0-914316-29-X

Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

Verapamil Therapy for Stable and Unstable Angina Pectoris: Calcium Channel Antagonists in Perspective

MILTON PACKER, MD, and WILLIAM H. FRISHMAN, MD

The papers that comprise this symposium summarize the international experience with verapamil in the management of patients with stable and unstable angina pectoris. These data formed the basis of approval of verapamil for the treatment of angina pectoris by the Cardio-Renal Advisory Committee of the Food and Drug Administration (FDA) in August 1981.

Symposium Perspective

Goal of the symposium: One year ago, we asked each investigator who presented data to the FDA to write a definitive review of a particular aspect of verapamil therapy, in which he would not only present his own data in a detailed and yet concise format, but also summarize the world's literature relevant to that specific topic. It was our impression that, although much had been written about verapamil, there was no central source of information and no consensus as to its role as an antianginal agent. The drug had been in clinical use for nearly 20 years, but most of the well-controlled data establishing its effectiveness had only become available within the last 3 years; clinicians were well aware of the anecdotal reports that dominated the literature 10 years ago, but the more recent well-controlled studies appeared to have received little attention. As a result, when planning this symposium, we asked each investigator to make each manuscript a timely critical review. When discussing pharmacology and drug interactions, we wanted only those data derived from studies using objective methods and controlled study designs. When discussing clinical efficacy, we wanted only conclusions based on randomized double-blind placebo-controlled trials. We asked each author to emphasize not only verapamil's advantages but its disadvantages; to underscore not only those clinical settings when the drug should be used, but also when it should be avoided. Our goal was to create a perspective, solidly based on concrete data and immediately translatable into clinical use.

The result is this symposium. Within its individual manuscripts we have effectively collected the world's experience on the *clinical* use of verapamil in ischemic heart disease into a single central source. Every paper in this symposium contains data obtained from patients enrolled in randomized clinical trials; in 9 papers, nearly all data presented is double-blind and placebo- or propranolol-controlled.

This symposium is divided into three parts; the first two appear in this month's issue and the third will appear in the November issue. The first part deals with the clinical pharmacology of verapamil, the second with its use in patients with angina at rest, and the third with its efficacy in patients with effort-related symptoms. The effectiveness of verapamil in the management of patients with supraventricular arrhythmias and hypertrophic cardiomyopathy is not specifically addressed.

From the Divisions of Cardiology, Departments of Medicine, The Mount Sinai School of Medicine, New York, New York; and the Albert Einstein School of Medicine, Bronx, New York.

Dr. Packer is the recipient of a Young Investigator's Research Award R23-HL-25055-02 from the National Heart, Lung, and Blood Institute, Bethesda, Maryland. Dr. Frishman is a Teaching Scholar of the American Heart Association, Dallas, Texas.

Verapamil: Pharmacologic and Hemodynamic Actions and Interactions

Historical perspective: First synthesized in 1962,[1] verapamil was the first compound described with the ability to selectively inhibit the transmembrane flux of calcium ions in excitable tissues.[2] Although initially believed to be a beta-adrenergic blocking drug,[3] it was found to exert peripheral and coronary vasodilator effects,[4] and thus underwent early evaluation as an antianginal agent[5]; subsequent studies demonstrated that the drug also had significant antiarrhythmic properties when tested in a variety of experimental preparations.[6] After 20 years, verapamil has emerged in the research laboratory as a valuable agent in the study of the role of the slow channel in the genesis of cardiac arrhythmias and as a chemical probe in studies of excitation-secretion and excitation-contraction coupling. In the clinical sphere, the drug has proved to have beneficial effects in the treatment of angina pectoris and supraventricular tachyarrhythmias.

Mechanism of antianginal effect: The mechanism of verapamil's antianginal actions appears highly complex. As discussed by Singh et al. in the first paper of this symposium, verapamil exerts vasodilator effects on the coronary and peripheral vessels as well as depressant effects on cardiac contractility and conduction; all four actions may be important in mediating the drug's antianginal effects. Verapamil is only a *mild* dilator of epicardial coronary vessels not in spasm, but the drug greatly attenuates sympathetically mediated and ergonovine-induced coronary vasoconstriction; these actions provide a rational basis for the drug's effectiveness in vasospastic ischemic syndromes. In patients with exertional anginal pectoris, verapamil's peripheral vasodilator actions and inhibitory effects on the sinus node serve to attenuate the increases in double product that normally accompany, and serve to limit, exercise. In addition, verapamil appears to exert effects on contractility, on stenosis diameter, and on ventricular compliance that may play important contributory roles in mediating its clinical benefits in ischemic heart disease.

Clinical significance of negative inotropic effects: The importance of verapamil's negative inotropic effects also is addressed by Singh et al. In patients with normal or moderately reduced ventricular function, verapamil's ability to reduce afterload likely counteracts its intrinsic negative inotropic effects, and thus, verapamil therapy is accompanied by little change in cardiac performance. However, in patients with a severely reduced left ventricular ejection fraction (less than 30 to 35%), the drug may produce hemodynamic deterioration.

Do these hemodynamic effects of verapamil differ from those of other calcium antagonists, such as nifedipine? Both drugs exert negative inotropic effects in isolated cardiac preparations,[7–9] but many cardiologists regard nifedipine as being less cardiodepressant, either because it is thought to possess less marked effects on cardiac contractility or because it may exert greater systemic vasodilator actions; the greater such vasodilator effects, the more complete is the neutralization of a drug's negative inotropic actions.[10] Although such beliefs concerning the relative effects of verapamil and nifedipine on cardiac performance may indeed be true, there are few comparative clinical data to support these views.

Much of the impression that verapamil exerts clinically important cardiac depressant effects may be a consequence of historical perspective. Because of its effectiveness in controlling supraventricular tachyarrhythmias, verapamil was commonly used (in the past) in patients with severely depressed ventricular function, who were particularly prone to experience such arrhythmias; although we now know that such use is inappropriate, the administration of verapamil to these patients occasionally produced severe exacerbations of heart failure.[11–14] Nifedipine, which has no antiarrhythmic actions, was not used in these clinical settings, and hence, little experience was gained with the use of this drug in patients with very poor cardiac function. Although nifedipine has been used as a vasodilator agent to improve cardiac performance in patients with symptoms of heart failure,[15,16] most of the patients treated in these studies had a left ventricular ejection fraction *greater* than 30% or a normal cardiac output and left ventricular filling pressure at rest; in such patients, neither verapamil nor nifedipine produces a decline in cardiac performance, and both drugs are usually well-tolerated. At Mount Sinai Hospital, using invasive monitoring techniques, both verapamil and nifedipine have been evaluated in patients with severe angina pectoris and an ejection fraction *less* than 30%. Although both drugs were well tolerated in most of these patients, worsening of ventricular performance was occasionally noted with both verapamil and nifedipine. Clearly, more work needs to be done to elucidate the safety and effectiveness of calcium antagonists in general in patients with severe left ventricular failure; until such data are available, we would advise caution with the use of all calcium channel blocking agents in such individuals.

Verapamil drug interactions: The next two papers in this issue review important interactions between verapamil and other cardiovascular agents. In the only report in this symposium which discusses the use of verapamil in the management of tachyarrhythmias, Klein and Kaplinsky review the interaction between verapamil and digitalis. Although digitalis has long been the principal drug used in patients with atrial fibrillation, the drug does not block the excessive ventricular rates that are seen in such patients during exercise. In contrast, verapamil effectively attenuates this excessive ventricular response and improves exercise capacity in such patients; when combined, the effects of verapamil and digoxin appear to be additive.

Verapamil increases serum digoxin levels in patients with atrial fibrillation. The mechanisms underlying this effect are similar to those proposed to explain the similar increase that accompanies the institution of quinidine therapy: a reduction in renal tubular secretion, in

metabolic clearance, and in the volume of distribution of digoxin.[17–19] However, the benefits of combined digoxin-verapamil therapy in patients with atrial fibrillation (previously outlined) are not a consequence of an increase in serum digoxin levels, because they are not reproduced by doubling the dose of digoxin in the absence of verapamil therapy. Recent evidence that nifedipine also increases serum digoxin levels[20] suggests that the renal or nonrenal clearance, or both, of digoxin may be mediated by calcium-dependent mechanisms. Hence, careful reassessment of digitalis therapy is needed whenever combined use of digitalis and calcium antagonists is contemplated.

Because both drugs possess negative chronotropic and inotropic effects, combined therapy of beta-adrenergic blocking drugs and verapamil has long been avoided. Packer et al. review the results of five hemodynamic and clinical studies concerning this interaction. The available evidence suggests that few cardiodepressant effects are seen when combined therapy of verapamil and low or moderate doses of propranolol are used; however, additive negative inotropic and chronotropic effects *are* observed when verapamil is administered to patients receiving large doses of propranolol. This appears to be particularly significant in patients with compromised left ventricular function (ejection fraction less than 30%) or in those taking drugs that attenuate alpha-adrenergic responses (for example, methyldopa). In patients who tolerate combined therapy, the benefits of such treatment are greater than those observed with the administration of either agent used alone. Although some have feared that verapamil would produce additive or synergistic effects on atrioventricular conduction, this has rarely been observed; adverse reactions appear largely hemodynamic rather than electrophysiologic. Because combined therapy of nifedipine and beta-blocking agents has also been reported to exacerbate clinical heart failure,[21,22] it appears prudent to exercise caution whenever combined calcium channel and beta-adrenergic blockade is used in the treatment of ischemic heart disease. Further large-scale studies are needed to determine the safety and efficacy of this therapeutic approach.

Verapamil: Studies in Angina at Rest

Verapamil versus placebo: Patients with angina at rest may have a wide spectrum of disorders, ranging from variant angina (S-T elevation) associated with angiographically normal coronary arteries to unstable angina with S-T depression or elevation associated with multivessel coronary artery disease. The elegant studies of Maseri et al.[23] suggest that coronary vasospasm plays a major role in the pathogenesis of ischemia in most patients with angina at rest, regardless of the coronary anatomy. Verapamil might therefore be expected to be effective in this syndrome because of its ability to block spontaneous and drug-induced spasm.[24] Such expectations are borne out by the double-blind placebo-controlled randomized trials reviewed by the three papers that comprise Part II. In a 9 month double-blind crossover trial, Winniford and co-workers demonstrate the effectiveness of verapamil in patients with variant angina, most of whom had normal coronary arteries. In two shorter but carefully controlled blinded trials, Mehta et al. and Parodi et al. establish verapamil's effectiveness in patients with unstable angina associated with severe obstructive coronary artery disease. In all three studies, verapamil not only greatly reduced the frequency of anginal attacks and the consumption of nitroglycerin but also decreased the total number of ischemic episodes as assessed by continuous Holter monitoring.

Verapamil versus propranolol and nifedipine: How does verapamil compare with other drugs advocated for the management of patients with angina at rest, such as propranolol and nifedipine? Parodi et al. address the comparative efficacy of verapamil and propranolol in their randomized blinded crossover trial. Only verapamil reduced symptomatic and asymptomatic episodes of ischemia; the effectiveness of propranolol was comparable with that of placebo. These findings are consistent with the concept that coronary vasospasm plays a crucial role in patients with angina at rest; in contrast, rather than provide any benefit, propranolol may exacerbate vasospastic phenomena.[25]

Winniford et al. directly address the comparative efficacy of verapamil and nifedipine in their report; a subset of their patients with variant angina received open-label nifedipine after completion of the placebo-controlled trial with verapamil. Both verapamil and nifedipine proved equally effective, and neither drug depressed ventricular function, either at rest or during exercise. However, adverse effects (headache, hypotension, and dizziness) occurred more frequently with nifedipine than with verapamil, and these reactions limited the dose of nifedipine that could be administered. These data indicate that in the management of patients with variant angina, the choice of a calcium antagonist is likely to be determined not so much by which drug is more effective, but by which agent is better tolerated by an individual patient.

Verapamil: Studies in Effort-Related Angina

Verapamil versus placebo: In Part III of this Symposium (to appear in the November issue) Weiner and Klein review the evidence derived from 6 independent double-blind placebo-controlled trials involving 193 patients and conclude that verapamil is a highly effective and safe drug for the treatment of exertional anginal discomfort.

Verapamil versus beta-blocking drugs: How does verapamil compare with other therapies advocated for the treatment of effort-related anginal symptoms? In their review of 9 double-blind randomized crossover trials, which compared verapamil therapy to treatment with beta-blocking drugs in 174 patients, Bala Subramanian et al. conclude that verapamil is as safe and effective as beta-blocking drugs in the treatment of patients with stable angina pectoris. In many studies cited, particularly those performed within the last 3 years, verapamil was superior to propranolol in prolonging the

duration of exercise. However, one must consider the possibility that patients entered into such recent studies were those who agreed to be subjects because they remained symptomatic despite previous therapy, which likely included a beta-blocking drug; this may have biased these trials toward finding a more favorable effect of verapamil.

In attempting to choose between verapamil and propranolol in the management of patients with effort-related symptoms, clinicians should keep in mind that some patients with angina do better with one drug than with the other. Unfortunately, we know little about how to predict with confidence the superior agent in a specific patient short of a therapeutic trial. In general however, verapamil can be used as an effective alternative in patients who remain symptomatic despite therapy with propranolol and as a first-line antianginal drug in patients with contraindications to beta-blockade.

As Frishman et al. point out, both verapamil and propranolol may be useful in the treatment of patients with both systemic hypertension and angina pectoris. Indeed, because of its peripheral vasodilator properties, verapamil may prove to be the superior antihypertensive agent. Because its long-term administration is well tolerated, verapamil merits further study in the management of patients with hypertension with and without coronary artery disease.

Verapamil versus nifedipine: Bala Subramanian et al. directly address the comparative effectiveness of verapamil and nifedipine in effort-related angina. In a double-blind randomized crossover trial involving 32 patients with stable anginal symptoms, verapamil was superior to nifedipine in prolonging exercise duration when either agent was used alone. Furthermore, verapamil was better tolerated than was nifedipine; 7 patients had increasing angina while taking nifedipine, whereas none did so while taking verapamil. A potential limitation of this study is that it used fixed doses of both drugs; however, the dose of nifedipine used (60 mg daily) was identical to that employed in the multicenter placebo-controlled trials of nifedipine recently conducted in the USA,[26] and the dose of verapamil used (360 mg daily) was similar to that administered in previous placebo-controlled evaluations. Larger doses of nifedipine might have produced greater effects, but such doses may have produced even more frequent adverse reactions. The authors conclude that verapamil is superior to and safer than nifedipine, when either drug is used alone in the treatment of exertional angina.

The finding that verapamil produces fewer adverse reactions than nifedipine is similar to the results of Winniford et al. reported earlier in this symposium. The two groups differ, however, in the types of side effects noted. Whereas the reactions noted by Winniford et al. (headache, hypotension, palpitations, peripheral edema) frequently required discontinuation of the drug or a reduction in dose, they were not life-threatening. Bala Subramanian et al., on the other hand, observed patients in whom therapy with nifedipine provoked episodes of ischemia. These differences may be attributable to differences in the patient populations evaluated; whereas most of the patients of Winniford et al. had normal coronary arteries, most of the patients of Bala Subramanian et al. probably had multivessel coronary artery disease. The greater frequency of adverse effects with nifedipine was recently confirmed by Dawson et al.[27] in a double-blind comparison of verapamil and nifedipine in patients with chronic stable angina; however, the types of adverse effects noted by these investigators were similar to those noted by Winniford et al.

The differences between nifedipine and verapamil noted by Bala Subramanian et al. may be the consequence of differences in their pharmacologic actions. Whereas both drugs exert antianginal effects by virtue of their peripheral vasodilator actions, such systemic vasodilation provokes sympathetically mediated reflex tachycardia, which (if left unopposed) might detract from a drug's antianginal effects and provoke adverse reactions (palpitations, headaches, and angina). This reflex sympathetic activation is not altered by nifedipine but is attenuated by verapamil, both directly by its inhibitory action on the sino-atrial node[28] and indirectly by a nonspecific antagonist effect on the sympathetic nervous system.[10] Although some view verapamil's effects on the cardiac conduction system as disadvantageous, such effects may contribute to the antianginal efficacy of the drug. On the other hand, optimal therapy with nifedipine in patients with effort-related angina appears to require combined treatment with a beta-blocking agent.

The relative effectiveness of verapamil and nifedipine in the treatment of patients with effort-related angina is likely to remain controversial. Whereas Bala Subramanian et al. found verapamil superior to nifedipine, Dawson et al.[27] found the two drugs equally effective in reducing the frequency of anginal attacks and in prolonging the duration of exercise. Both trials were double-blind and administered similar doses of both agents. The major limitation of both studies, however, is that the investigators compared the effectiveness of verapamil and nifedipine when either agent was used alone. In view of the widespread use of beta-blocking drugs, both in the management of anginal symptoms and in the prevention of future ischemic events in patients recovering from a myocardial infarction,[29] an important question remains regarding the relative efficacy and safety of verapamil and nifedipine when administered to patients receiving beta-adrenergic blocking agents. The choice of a first-line calcium antagonist in the management of patients with effort-related angina awaits the completion of such randomized comparative trials.

Clinical application of verapamil: The last three reports in this symposium review special topics of importance in the clinical use of verapamil in the individual patient with angina pectoris.

In examining the relationship between its antianginal effect and plasma levels of verapamil, Frishman et al. suggest that the optimal dose of verapamil in the management of patients with stable angina pectoris may be

either 320 mg daily (80 mg four times daily) or 360 mg daily (120 mg three times daily). As Pine et al.[30] have demonstrated, increments in the dose of verapamil beyond 360 mg daily is accompanied by only minor further improvements in exercise tolerance and are not infrequently accompanied by a significant increase in adverse reactions. Our own preference is to begin verapamil therapy with a dose of 80 mg four times daily and, if this proves effective, to alter the regimen to 120 mg three times daily in an effort to enhance patient compliance. Whether such observations and conclusions are applicable to the patient with angina at rest is unknown.

Scheidt et al. address the question of verapamil's long-term antianginal effectiveness. Long-term studies, by their very nature, are usually anecdotal because it is difficult to maintain placebo controls for long periods once a therapeutic intervention has been shown effective in an individual patient. This study attempts to improve on the usual anecdotal format by following up 66 patients, in whom the effectiveness of verapamil had been established in randomized double-blind crossover trials and who were then treated for 1 year. The beneficial effects of verapamil in most patients with stable angina pectoris in this study were maintained throughout the period of follow-up. In 21 patients these sustained effects were demonstrated by objective tests of exercise tolerance over the entire 12 months, and exercise tolerance deteriorated when verapamil therapy was discontinued.

The comparative effects of abrupt withdrawal of verapamil and propranolol are compared by Frishman et al. in the final report in the symposium. Of their patients with stable effort-related symptoms, 10% had a severe clinical exacerbation of the anginal syndrome on withdrawal of propranolol; no patient had rebound symptoms when verapamil was abruptly discontinued.

Acknowledgment

We would like to express our great appreciation to the Knoll Pharmaceutical Company, who not only sponsored the publication of this symposium, but more importantly, supported the clinical investigations and trials that constitute the content of these reports. We are also greatly indebted to Dr. Simon Dack, who advised, inspired, and supported us through the difficult task of compiling and editing this work.

Pharmacologic and Hemodynamic Mechanisms Underlying The Antianginal Actions of Verapamil

BRAMAH N. SINGH, MD, DPh (Oxon), FRCP (Lond), CHRISTOPHER Y. C. CHEW, MD, MRCP (Lond), MARTIN A. JOSEPHSON, MD, and MILTON PACKER, MD

The pharmacologic and hemodynamic effects of verapamil are the result of its selective inhibitory action on the slow channel in cardiac muscle and its propensity to block transmembrane calcium influx in vascular smooth muscle and to nonspecifically antagonize sympathetic excitation. In patients with normal or moderately reduced ventricular function, verapamil's ability to reduce afterload counteracts its intrinsic negative inotropic effects and therefore a reduction in ventricular performance is not seen. In patients with a severely reduced ventricular ejection fraction and high ventricular filling pressures, however, the drug may produce clinical and hemodynamic deterioration. Computer-assisted angiographic analysis shows that verapamil dilates normal as well as narrowed epicardial coronary vessels and reverses ergonovine- and sympathetically provoked coronary vasoconstriction. Intravenous administration of verapamil reduces coronary arterial resistance and enhances coronary sinus flow with variable effects on myocardial oxygen consumption. The drug prevents the ischemic consequences of angina produced by atrial pacing; after verapamil administration, pacing-induced lactate production is lessened, and ischemia-related declines in left ventricular ejection fraction are prevented. During chronic therapy the effects of verapamil on regional and global ventricular function are similar to those of propranolol during supine bicycle exercise. However, verapamil has significantly less effect on rate-pressure product at rest and during exercise, which suggests that its antianginal mechanism of action, unlike that of beta-blocking agents, may not be related solely to a reduction in oxygen demand. These data indicate that the mechanisms underlying the antianginal effects of verapamil are complex and are likely to be multifactorial.

Although verapamil hydrochloride was introduced as a coronary vasodilator and antianginal agent over 20 years ago,[1] only recently has detailed knowledge of its pharmacologic properties become available.[2–4] Verapamil is the prototype of a group of drugs designated as *calcium antagonists* or *slow channel inhibitors*.[2] The delineation of this class of drugs closely followed the demonstration in cardiac muscle that depolarization during the passage of an electrical impulse is mediated by two discrete current systems. The first is a fast sodium current (fast response) which is selectively inhibited by tetrodotoxin and local anesthetics. The second is a slow current system (slow response) which is carried primarily by calcium and is responsible for excitation-contraction coupling in cardiac muscle. It is the selective inhibition of the slow calcium current that characterizes the fundamental property of the calcium antagonists.[2,5] In the heart, the sinoatrial and atrioventricular nodes are slow channel dependent and are the main loci of action of the slow channel inhibitors. In addition, these agents block the transmembrane flux of calcium in cardiac muscle and vascular smooth muscle, especially in the coronary and peripheral arteries;[6] the precise mechanisms involved in these latter effects are unclear because a slow channel has not been identified in smooth muscle tissues.

In this report the pharmacologic and hemodynamic responses to verapamil are discussed with particular

reference to those features of drug action that provide a framework for understanding the potential mechanisms that underlie its antianginal effects.

Hemodynamic Effects of Verapamil

Pharmacologic considerations: The effects of verapamil in the intact circulation are the result of a complex interplay of the direct effects of the drug on the myocardium and the reflex responses provoked by the action of the drug on peripheral vessels; hence, verapamil's effects in animals and in man are not comparable to those seen in isolated muscle preparations.[2,4,7] In isolated cardiac muscle, verapamil exerts a profound negative inotropic effect and a marked depressant effect on impulse formation and conduction in the sinoatrial and atrioventricular nodes; these in vitro depressant effects can be competitively antagonized by calcium and by catecholamines.[7] Verapamil also exerts systemic and coronary vasodilator effects because of its direct action on potential-dependent and receptor-dependent calcium channels in peripheral vessels.[8] These systemic vasodilator actions elicit activation of reflex sympathetic forces, which serve to offset the direct negative effects of the drug on cardiac contractility and conduction. The structures most likely to exhibit verapamil's direct depressant effects are those with intrinsic disorders of contractility or conduction or those in whom sympathetic influences have been pharmacologically attenuated.[9]

Hemodynamic studies in dogs: In open chest anesthetized dogs, Ross and Jorgensen[10] observed that verapamil exerted notable depressant effects on cardiac performance; however, the hypotensive effects of the drug were related to a concomitant reduction in systemic vascular resistance if the dose of verapamil did not exceed 0.25 mg/kg intravenously. In unanesthetized closed chest dogs, the direct cardiodepressant effects of the drug were less pronounced; verapamil produced dose-dependent peripheral vasodilation with reflex *increases* in myocardial contractility and heart rate.[11] Pretreatment with propranolol attenuated reflex cardiac stimulation but did not alter the peripheral vasodilator responses, indicating that the vascular effects of the drug were mediated through mechanisms independent of peripheral beta-adrenoreceptor stimulation.[12] A direct myocardial depressive action became apparent only when a dose of verapamil greater than 0.3 mg/kg was used.

Hemodynamic studies in stable coronary artery disease: Although a number of hemodynamic studies have evaluated the hemodynamic effects of intravenous verapamil in man,[13–20] detailed hemodynamic studies in patients with cardiac disease only recently have been reported[13,16] (Table I).

Singh and Roche[13] assessed the effects of 10 mg of intravenous verapamil in 20 patients with coronary or rheumatic heart disease. Verapamil produced a moderate decrease in mean arterial pressure consequent to a decline in systemic vascular resistance without a change in cardiac and stroke volume indexes. Cardiac output would normally be expected to increase after any drug-induced decrease in peripheral resistance; failure to observe such an increase after verapamil was likely the result of a moderate direct depressant effect of the drug on myocardial contractility. This effect was evidenced by a drug-induced decrease in left ventricular dP/dt max and an increase in left ventricular end-diastolic pressure (Fig. 1). In a separate study of 20 patients with coronary artery disease, Ferlinz et al.[16] administered verapamil as an 0.1 mg/kg bolus followed by an 0.005 mg/kg/min infusion, and observed systemic hemodynamic changes comparable to those seen by Singh and Roche;[13] however, Ferlinz et al.[16] observed significant increases in cardiac output and left ventricular ejection fraction after verapamil (Table I). Most hemodynamic and ventriculographic studies have not demonstrated an increase in cardiac output and ejection fraction after verapamil administration[14,19,20] and therefore are in agreement with the findings of Singh and Roche.[13]

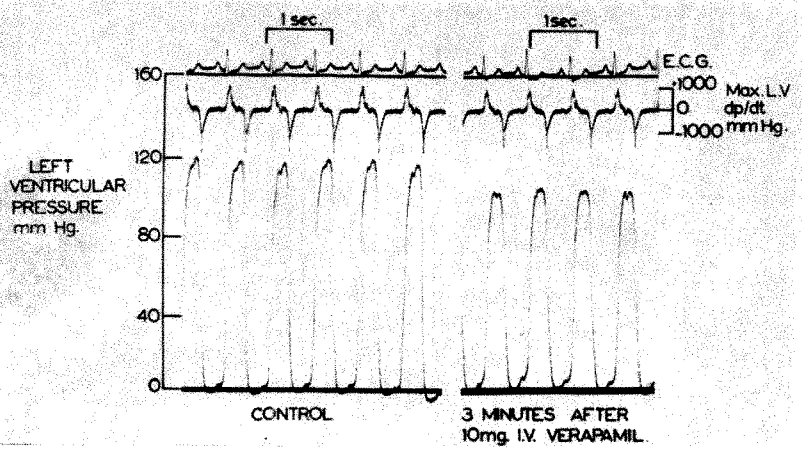

FIGURE 1. Effects of verapamil on left ventricular contractility in a patient with coronary artery disease. The left ventricular pressure and the first derivative of the pressure (LV dP/dt max) were obtained by high fidelity catheter tip manometry and electronic differentiation, respectively. Verapamil diminished peak systolic left ventricular pressure and increased left ventricular end-diastolic pressure, but produced only a small decrease in LV dP/dt max. There was no change in heart rate. (Reproduced, with permission, from Singh and Roche.[13])

It should be emphasized that the two studies just cited were performed in patients with preserved left ventricular function. The left ventricular ejection fractions before verapamil in all of the patients evaluated exceeded 35% and averaged 55 to 60%, and the left ventricular end-diastolic pressures averaged 11 to 12 mm Hg.[13,16] Therefore, in patients without heart failure, the expected myocardial depressant effect of verapamil is largely offset by its vasodilator actions on the peripheral circulation. Although ventricular filling pressures increase modestly after drug administration, cardiac and stroke volume indexes remain unchanged in patients with preserved left ventricular function. These data are consistent with clinical experience that verapamil produces little deleterious hemodynamic effects in patients without cardiac failure.

Verapamil in acute myocardial infarction: Although verapamil has been used to treat supraventricular tachycardia in patients with acute myocardial infarction,[2,4] few detailed hemodynamic studies have been reported in this clinical setting. Chew et al.[14] measured changes in systemic hemodynamics and radionuclide-determined left ventricular ejection fraction after intravenous verapamil (0.145 mg/kg bolus followed by 0.005 mg/kg/min infusion) in 7 patients with acute uncomplicated myocardial infarction (mean pulmonary capillary wedge pressure below 18 mm Hg) and in 15 patients with chronic stable angina without infarction (Table II). The hemodynamic effects of verapamil in the two groups of patients were similar and were comparable to the hemodynamic responses in other studies that evaluated patients with stable coronary artery disease with preserved left ventricular function.[15,16] Therefore, verapamil does not exert a significant cardiac depressant effect in patients with uncomplicated recent myocardial infarction.

The administration of verapamil orally also produces few cardiodepressant effects in patients with acute

myocardial infarction. Theroux et al.[12] evaluated the hemodynamic responses to a single *oral* dose of 160 mg of verapamil in 10 such patients (Fig. 2). Mean arterial pressure decreased moderately without significant effects on heart rate or cardiac index. The data demonstrate that verapamil can safely be administered intravenously or orally in patients with acute myocardial infarction without clinical evidence of cardiac failure.

Verapamil in left ventricular dysfunction: In contrast to the experience just outlined in patients with preserved left ventricular function, Chew et al.[14] showed that verapamil may exert significant cardiodepressant effects in patients with severely impaired left ventricular performance before therapy. In 3 patients with a severely reduced left ventricular ejection fraction (less than 35%) and markedly elevated left ventricular filling pressures (greater than 20 mm Hg), hemodynamic and clinical deterioration occurred after intravenous verapamil administration; mean arterial pressure and cardiac index decreased in association with an abrupt increase in pulmonary capillary wedge pressure (25.7 to 33.3 mm Hg). In contrast, in patients with pulmonary capillary wedge pressures less than 20 mm Hg or a left ventricular ejection fraction greater than 30%, the same doses of intravenous verapamil produced only modest increases in left ventricular filling pressures, no change in left ventricular ejection fraction, and no clinical deterioration. These data indicate that patients with impaired ventricular function are particularly susceptible to verapamil's negative inotropic effects; the reduction in ventricular afterload resulting from the drug's action on peripheral vessels is insufficient to offset the depressant effects of the drug on the myocardium. Verapamil can exacerbate clinical evidence of congestive heart failure and should be used cautiously in patients with a markedly decreased left ventricular ejection fraction (less than 30 to 35%).

Potential Mechanisms of Antianginal Actions of Verapamil

Primary and secondary angina: Myocardial ischemia occurs when a significant imbalance is created between myocardial oxygen demand and oxygen delivery to the heart. In obstructive coronary artery disease, angina may occur when myocardial oxygen requirements increase secondary to increases in heart rate, blood pressure, ventricular wall tension, or contractility. Because a reduction in coronary blood flow is not the initiating event in such a situation, angina occurring under such conditions has been termed "secondary." Alternatively, angina may result from a "primary" reduction in coronary flow (due to coronary vasospasm) without a change in myocardial oxygen demands and may occur in patients with either normal coronary arteries or those with varying degrees of arteriosclerotic obstruction.[22,23] Most often, primary and secondary angina do not exist as discrete entities; the relationship of the clinical spectrum of myocardial ischemic syndromes and the dynamic pathology of coronary arteriosclerosis was recently emphasized by the quantitative studies of Brown et al.[23,24] To elucidate potential mechanisms of action of antianginal agents, attention must be focused on both drug-induced changes in myocardial oxygen consumption and coronary vasomobility.[25,26]

To obtain insight into the nature of its beneficial actions, three separate studies were performed to examine the effects of verapamil on (1) coronary hemodynamics and vasomobility, (2) pacing-induced myocardial ischemia, and (3) exercise-induced ischemic ventricular dysfunction.

Effects of verapamil on coronary hemodynamics and vasomobility: Verapamil exerts direct vasodilator actions on coronary and systemic vessels in a variety of experimental preparations.[1,27,28] Nayler et al.[12] demonstrated in dogs that verapamil, like propranolol, decreased myocardial oxygen demands; however, whereas propranolol consistently increased coronary vascular resistance, verapamil *decreased* coronary resistance, even during the hypotensive phase of the drug's action.

The effects of verapamil on coronary hemodynamics and vasomobility have been examined in a number of studies in man. Using myocardial clearance of radioactive rubidium as an index of coronary blood flow, Luebs et al.[29] noted a marked increase in coronary blood flow after intravenous verapamil in patients without coronary disease but not in patients with diseased ves-

sels. Simonsen[30] noted that both verapamil and nifedipine reduced coronary arteriolar resistance in patients with coronary artery disease with little or no change in coronary sinus blood flow or myocardial oxygen consumption. In contrast, Ferlinz and Turbow[31] found that in patients with coronary artery disease, intravenous verapamil *decreased* coronary sinus blood flow without significant changes in coronary vascular resistance. They postulated that verapamil exerted its most important effects by reducing systemic vascular resistance and thereby reducing myocardial oxygen consumption; the changes in coronary artery blood flow after verapamil administration were secondary to the decrease in myocardial work and hence did not play a primary role in the drug's antianginal actions.

Our own detailed observations (Chew et al.[26]) support the work of Simonsen.[30] In our study, coronary and systemic hemodynamics were determined during continuous intravenous verapamil infusion; alterations in coronary vasomobility were assessed by a computer-assisted quantitative angiographic technique[25] that permitted the computation of cross-sectional areas of "normal" and stenotic segments of coronary arteries in addition to the calculation of stenosis flow resistance.[26] The mean data for systemic vascular resistance, coronary vascular resistance, and coronary sinus blood flow (as determined by continuous thermodilution) are shown in Figure 3. A typical computer printout of a 3-dimensional reconstruction of a coronary artery lesion plus its proximal and distal segments before and during verapamil infusion is presented in Figure 4. In these studies systemic and coronary vascular resistance decreased ($p < 0.01$) without a change in coronary sinus blood flow or myocardial oxygen consumption. Fifty % of the coronary lesions analyzed in both "normal" and stenosed areas dilated significantly with verapamil with a mean reduction in estimated stenosis flow resistance. However, these changes in coronary caliber were less striking when compared with those of nitroglycerin, which produced large vessel coronary vasodilation 2 to 3 times greater than did verapamil.

These observations indicate that in coronary artery disease, verapamil decreases systemic and coronary vascular resistance but exerts variable effects on coronary sinus blood flow and myocardial oxygen consumption. These data support the experimental work by Harder et al.[32] in which verapamil blocked calcium-dependent action potentials in both the large and small coronary vessels. However, compared with nitroglycerin, verapamil is only a mild epicardial coronary vasodilator; compared with dipyridamole, verapamil exerts only modest effects on coronary vascular resistance.[16,33] These relatively mild coronary vasodilator actions of verapamil in vessels not in spasm do not ne-

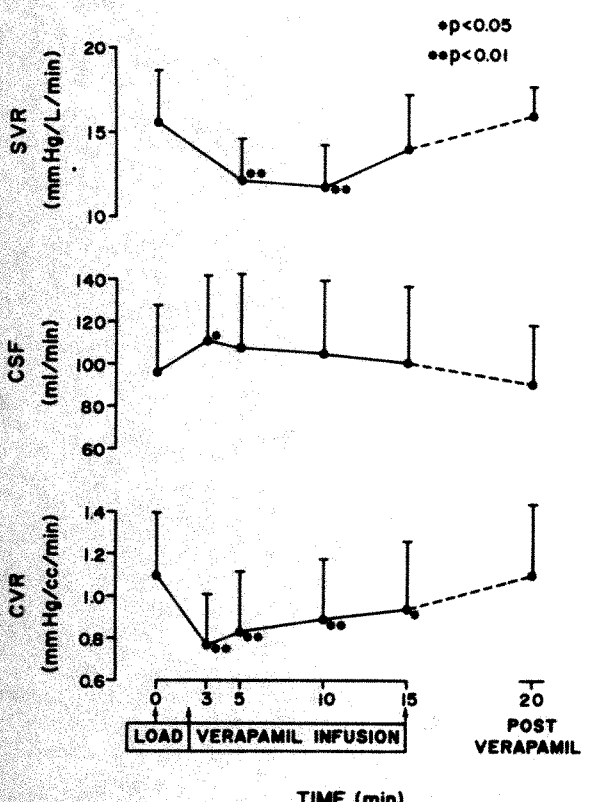

FIGURE 3. Effects of intravenous verapamil on systemic vascular resistance (SVR), coronary sinus flow (CSF), and coronary vascular resistance (CVR). The data presented are means ± standard deviation. Note that CVR and SVR decrease as CSF increases. These changes are consistent with the coronary vasodilator properties of verapamil. (Reproduced, with permission, from Chew et al. Clin Invest Med 1980;3:151–158.)

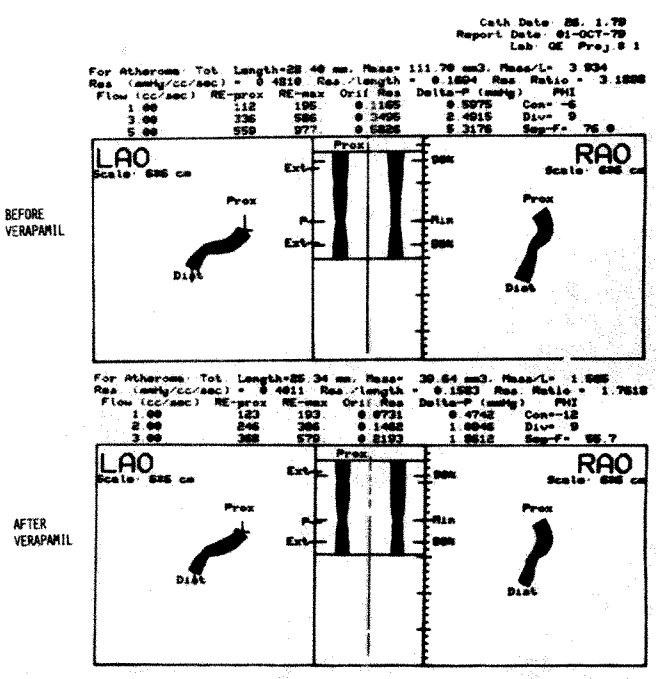

FIGURE 4. Computer printout of a coronary lesion analyzed before **(upper panel)** and after **(lower panel)** verapamil administration. LAO = left anterior oblique view; RAO = right anterior oblique view. Note the decrease in orifice resistance after verapamil consistent with the increase in vessel diameter at the site of maximal stenosis. (Reproduced, with permission, from Chew et al. Clin Invest Med 1980;3:151–158.)

gate the proven efficacy of verapamil in vasospastic angina.[34] Recent studies using quantitative coronary angiography show that intravenous verapamil significantly inhibits sympathetic-mediated and ergonovine-induced coronary vasoconstriction in diseased human coronary vessels to an extent that greatly exceeds its mild effects on such vessels in the basal state.[35] These data not only provide a rational basis for the use of verapamil in Prinzmetal's variant angina but also suggest that dilation of coronary stenosis may contribute to the drug's antianginal action when ischemia is produced consequent to a complex interaction between fixed obstruction and dynamic alterations in coronary artery caliber.[23]

Effects of verapamil in pacing-induced angina: The beneficial effects of verapamil on ischemic changes induced by incremental atrial pacing have been demonstrated in two independent studies. In 12 patients with coronary artery disease evaluated by Ferlinz and Turbow,[31] atrial pacing provoked anginal pain accompanied by S-T segment depression and a decrease in lactate extraction. After the administration of verapamil, repeat atrial pacing did not produce anginal pain in many patients and the time preceding angina was increased in the others; pacing-induced electrocardiographic and metabolic evidence of ischemia was also ameliorated. Using a similar protocol in 8 patients with coronary artery disease, Hecht et al.[15] noted that verapamil attenuated the magnitude of pacing-induced ischemic left ventricular dysfunction. Before verapamil, rapid pacing induced chest pain, a progressive decrease in left ventricular ejection fraction associated with new regional wall abnormalities, and a decline in myocardial lactate extraction (Fig. 5). When pacing was repeated during verapamil administration, atrial pacing to the same rate produced no or only minimal chest discomfort, did not decrease global or regional left ventricular ejection fraction, and did not alter lactate extraction (Fig. 5). Before verapamil, pacing-induced ischemia was accompanied by an increase in mean arterial (98.0 to 110.2 mm Hg) and pulmonary capillary wedge pressures (9.1 to 12.5 mm Hg); after verapamil, pacing did not alter systemic arterial or left ventricular filling pressures significantly (85.5 to 92.5 and 10.8 to 11.4 mm Hg, respectively).

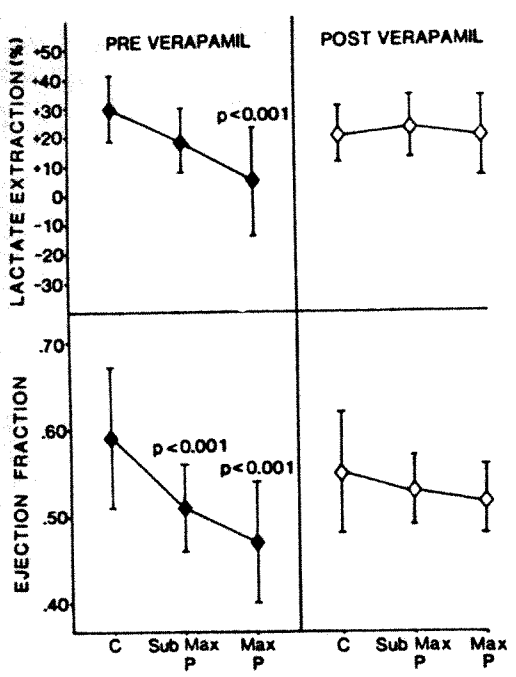

FIGURE 5. Changes in myocardial lactate extraction and left ventricular ejection fraction before and after verapamil infusion during coronary sinus pacing in patients with coronary artery disease. The data represent mean values ± standard deviation. Verapamil abolishes the abnormalities of lactate extraction and prevents the significant reduction of the ejection fraction at submaximal as well as maximal coronary sinus pacing. Max P = maximal pacing; Sub Max P = submaximal pacing. (Reproduced, with permission, from Hecht et al.[15])

The reduction in systemic arterial pressures and systemic vascular resistance that follows verapamil administration might be expected to reduce myocardial work and hence contribute to the antianginal effects of the drug. A *reduction* in myocardial oxygen consumption accompanied decreases in systemic pressure in the investigations of Ferlinz and Turbow,[31] who noted that verapamil *decreased* coronary sinus blood flow and did not alter coronary vascular resistance. This finding is in contrast to the mild coronary vasodilator effects without change in myocardial oxygen consumption noted after verapamil administration by Chew et al.,[26] Luebs et al.,[29] and Simonsen.[30] The reasons underlying the different results are unclear from the available data; however, verapamil likely exerts different effects on myocardial oxygen consumption and coronary sinus blood flow in different patients and in different clinical settings.

All these studies provide objective evidence for the antianginal actions of verapamil in coronary artery disease. The relative importance of the drug's effects on coronary vascular resistance and myocardial oxygen consumption in mediating these antianginal actions requires further study.

Effects of verapamil on myocardial performance during exercise: Josephson et al.[36] compared the effects of oral verapamil (480 mg/day) with those of oral propranolol (320 mg/day), each administered for 7 days, on the radionuclide global and regional left ventricular ejection fraction at rest and during supine bicycle exercise in 15 patients with coronary artery disease using a single-blind placebo cross-over protocol. Neither propranolol nor verapamil depressed the resting left ventricular ejection fraction, and both drugs were equally effective in preventing the exercise-induced decline in the left ventricular ejection fraction and in ameliorating exercise-induced electrocardiographic and segmental wall abnormalities (Fig. 6). Propranolol's beneficial effects were accompanied by marked attenuation of exercise-induced increases in heart rate (24.5%), systolic blood pressure (8.7%), and rate-pressure product (34.5%). Although verapamil therapy also decreased all 3 variables, the magnitude of its effect on heart rate (10.3%), systolic pressure (4.6%), and rate-pressure product (14.6%) was significantly less than that

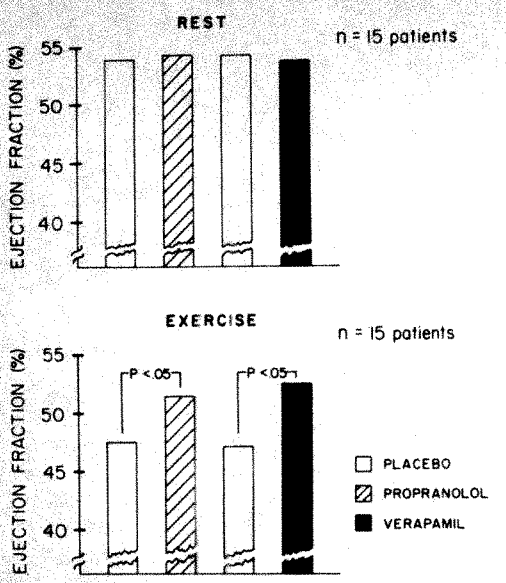

FIGURE 6. Comparative effects of verapamil and propranolol on left ventricular ejection fraction at rest and after supine bicycle exercise. Neither drug depressed resting left ventricular ejection fraction, and both prevented the decrease in ejection fraction that occurred on placebo during identical work loads. The data indicate that verapamil and propranolol have comparable antiischemic effects.

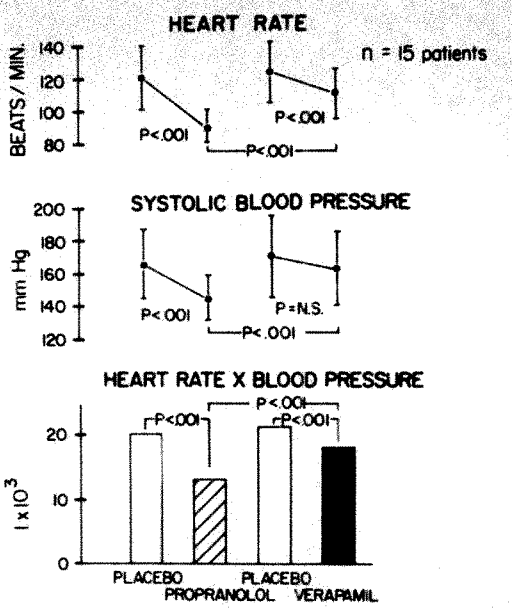

FIGURE 7. Comparative effects of orally administered propranolol and verapamil relative to that of a placebo on heart rate, blood pressure, and rate-pressure product during supine bicycle exercise in patients with coronary artery disease. Propranolol reduced rate-pressure product more than did verapamil at the identical exercise work load.

of propranolol (Fig. 7). Frishman et al.[37] and Johnson et al.[38] also noted that verapamil reduced the resting and exercise rate-pressure product significantly less than did propranolol despite comparable antianginal effects.

These data suggest that, although verapamil and propranolol exhibit comparable effectiveness in reducing the ischemic consequences of exercise stress in patients with coronary artery disease, the mechanisms underlying their beneficial effects probably differ significantly. The beneficial actions of propranolol and other beta-adrenergic blocking drugs appear to be primarily exerted by a decrease in myocardial oxygen requirements. However, verapamil exerts similar effects on myocardial ischemia while affecting the major determinants of oxygen consumption far less than does propranolol. Hence, a reduction in oxygen demand does not appear to be the sole mechanism involved in the antianginal effects of verapamil; decreases in coronary vascular resistance[26] and improvements in ventricular compliance[39] are likely to play additional and important roles.

Clinical Implications

The mechanisms underlying verapamil's antianginal effects are highly complex and likely involve the interaction of numerous circulatory responses. The drug is a mild dilator of epicardial coronary vessels but markedly attenuates sympathetically mediated and ergonovine-induced coronary vasoconstriction. These actions provide a rational basis for the drug's salutary effects in vasospastic ischemic syndromes in the presence or absence of coronary artery disease. The mechanisms underlying verapamil's beneficial actions in exertional angina are less clear. The drug attenuates the ischemic consequences of atrial pacing and of supine bicycle exercise in patients with angina pectoris; however, these changes are accompanied by minimal increases in coronary sinus blood flow and modest decreases in the principal determinants of myocardial oxygen consumption. Verapamil exerts antianginal benefits similar to those of propranolol, but indexes of myocardial oxygen consumption are reduced more strikingly by propranolol than by verapamil. Verapamil may exert its effects in exertional angina not only by decreasing myocardial oxygen consumption, but also by stenosis dilation and by improving ventricular compliance. These concepts provide a rational basis for the use of verapamil in patients with coronary artery disease regardless of whether ischemia results from primary (vasospastic) or secondary (stress-induced) mechanisms. Differences in the mechanisms underlying the antianginal actions of beta-antagonists and slow channel inhibitors suggest that additive effects might be obtained when these two classes of compounds are used in combination; preliminary studies have confirmed this important therapeutic possibility.[40]

Verapamil and Digoxin: Their Respective Effects On Atrial Fibrillation and Their Interaction

HERMAN O. KLEIN, MD and ELIESER KAPLINSKY, MD

Although digitalis has long been used in the management of patients with atrial fibrillation (AF), it does not block the excessive increase in ventricular rate which occurs in such patients during mild exercise; in contrast, this inappropriate response is effectively blocked by verapamil. During regular sinus rhythm, the atrioventricular (A-V) node works well as a *delaying* structure (the P-R interval), and the ventricular rate is a function of the sinus rate only; however, in AF, the A-V node has to adopt the role of a *filter* for numerous wave fronts of activity, a function it fulfills poorly, especially during the enhanced sympathetic responses and decreased vagal tone that accompany exercise. In patients with AF, during exercise, these autonomic alterations override the vagal effects of digitalis on the A-V node, but verapamil remains effective by virtue of its direct action on the slow channel ionic fluxes within the A-V nodal cells. The beneficial effect of verapamil on ventricular rate is accompanied by a significant improvement in maximal exercise capacity in patients with AF receiving long-term oral verapamil therapy; thus, it appears superior to digoxin in the treatment of chronic AF.

Verapamil significantly increases serum digoxin concentration by reducing renal and nonrenal digoxin clearance and, possibly, by reducing its volume of distribution. Serum digoxin concentrations also are increased by nifedipine. The clinical implications of these interactions are unclear; at present it is recommended that the dose of digoxin be reduced when therapy with a calcium antagonist is given concomitantly.

About digitalis in atrial fibrillation: "Although it is usually possible to control the rate . . . at rest or quietly exercising, it is rarely possible to control the rates adequately in conditions of freer exercise."

Sir Thomas Lewis, 1934[1]

About verapamil in atrial fibrillation: ". . . Verapamil is the most effective and probably the safest drug for effecting a conduction delay or block within the A-V node."

L. Schamroth, 1980[2]

Although much attention has been given to the use of verapamil in the acute management of supraventricular tachyarrhythmias,[3–6] there are comparatively few data concerning its usefulness in the long-term treatment of these arrhythmias. This article reviews the use of verapamil in the long-term control of excessive ventricular rates in patients with atrial fibrillation. The interaction of verapamil and digoxin is also discussed.

Effects of Digitalis and Verapamil in Atrial Fibrillation

Digitalis in the Management of Atrial Fibrillation

Historical perspectives: 80 years of digitalis therapy: The two foregoing quotations highlight the evolution that is gradually taking place in the treatment of patients with AF. MacKenzie[7] first demonstrated that digitalis slows the ventricular rate in patients with AF; however, he administered the drug to patients with congestive heart failure, so that the decrease in heart

rate may have been related in part to the improvement in cardiac performance that follows digitalis therapy rather than to the direct effects of the drug on atrioventricular (A-V) conduction. Nevertheless, digitalis became the keystone of the treatment of both acute and chronic AF and remained so for nearly 80 years, in spite of the observations of Sir Thomas Lewis.[1] However, Blumgart[8] and others[9–18] showed that although digitalis slowed the ventricular rate at *rest* in patients with AF, it failed to do so during exercise. In the words of Gold et al.[12]: "In general, our experience is that as a group patients with auricular fibrillation without heart failure are rather more resistant to slowing by digitalis."

Other investigators have defended the role of digitalis in the management of patients with AF. Modell et al.[19] advocated the use of incremental doses of the drug followed by testing for adequacy of dosage by determining the increase in heart rate after atropine. Redfors[20–22] reported that digoxin attenuated exercise-induced tachycardia in patients with AF; however, the decrease was small (13%), even when the dose and plasma concentration of digoxin were doubled.

Controlled clinical trials of digitalis in AF: We recently reinvestigated the response of patients with AF to digitalis in two separate studies. In the first, the ventricular response at rest and during exercise was evaluated in 23 patients with chronic AF during treatment with their usual dose of digoxin (0.25 to 0.50 mg daily) and again after we raised the daily digoxin dose so as to triple serum digoxin concentrations (0.6 to 1.8 ng/ml). We noted that increases in the dose of digoxin failed to decrease the ventricular rate at rest or during mild exercise (450 kiloponds per minute [kpm] for 2 minutes) significantly more than did the lower dose of digoxin.[23] Whether low doses of digitalis were beneficial was not determined because patients were not evaluated while receiving no therapy.

In the second study, 24 patients with chronic atrial fibrillation without congestive heart failure were evaluated as part of a comparative trial of digitalis and verapamil.[24] Ventricular rates were assessed at rest and during mild exercise (300 kpm for 3 minutes) *before and after* the administration of digoxin, administered in 2 different daily oral doses, 0.25 mg and 0.50 mg daily, and in randomized order. Chronic oral digoxin therapy produced moderate decreases in the ventricular response at rest (108 beats/min on no therapy, 95 beats/min on digoxin 0.25 mg daily, and 88 beats/min with 0.5 mg daily), but exerted minimal effects during exercise (160 beats/min on no therapy, 155 beats/min with digoxin 0.25 mg daily, and 148 beats/min with digoxin 0.50 mg daily), despite a mean serum digoxin concentration of 1.71 mg/ml achieved with a daily dose of 0.5 mg (Fig. 1).[24] The excessive ventricular response during mild exercise (300 kpm for 3 minutes) was similar during all three treatment periods; the mean heart rate with 0.5 mg digoxin was reduced only by 8%, which, although significantly less ($p < 0.025$) than the untreated response, remained out of proportion to the minimal exercise performed.

Thus, digoxin has major limitations in the long-term management of patients with AF. To understand the reasons for the failure of digoxin therapy, a brief review of the physiology of atrioventricular conduction in AF is necessary.

A-V Node in AF

The irregularity and apparent randomness of the ventricular rate in AF is the ultimate outcome of a complex interplay of several factors, which can be grouped into three major categories: (1) the nature of the electrical input into the A-V node, that is, the number, irregularity, and direction of atrial impulses that bombard the approaches to the A-V node; (2) the responsiveness of A-V nodal cells and the preservation of intranodal conduction; and (3) the modulation of both (1) and (2) by extracardiac factors such as sympathetic and parasympathetic influences and the effects of drugs.

Atrial electrical input: In AF, most of the 400 to 800 impulses that bombard the approaches to the A-V node are blocked at the atrionodal junction or in the upper part of the A-V node. The ability of the remaining impulses to excite the successive layers of A-V nodal cells and traverse the entire A-V node is predicted upon the organization and direction of the excitatory wave front.[25,26] An increase in vagal tone or the institution of digitalis therapy could decrease the ventricular rate not only by their well-established effects on intranodal conduction, but also by increasing the electrical input to the A-V node at this point. By decreasing the atrial refractory period and increasing atrial conduction velocity, acetylcholine and digitalis may increase the number of, and thereby the disorganization of, the atrial impulses that invade the upper part of the A-V node[27–31]; this reduces the ability of these impulses to traverse the A-V node. Verapamil also may increase the atrial rate in some patients with AF[32] and thus could exert a similar negative influence on the organization of the excitatory wave fronts.

A-V nodal transmission of impulses: Propagation of the excitatory wave front across the A-V node takes place with a relatively low margin of safety. The anatomic nature and arrangement of the A-V nodal fibers, their dependence on ionic transfer across "slow channels" for activation, and their time-dependent recovery from refractoriness are responsible for the relative ease with which impulses are delayed or blocked within the A-V node, especially at high and irregular rates.[25,33–36] Decremental conduction[25,36] and inhomogeneity of propagation[25] also may affect the propagation of subsequent atrial impulses by setting up various degrees of inexcitability in successive layers of cells of the A-V node,[35–41] an effect called "concealed conduction" by Langendorf.[38]

Modulating factors: autonomic influence and drugs: The complex events that result in the apparently random ventricular response to AF are strongly influenced by autonomic nervous system activity. Ace-

tylcholine markedly impairs A-V conduction, both by depressing the amplitude and rate of rise of the action potentials in the middle region of the A-V node and by reducing the effectiveness of the upper nodal cell potentials as a stimulus for the middle region.[33,42,43] Catecholamines markedly enhance A-V conduction by increasing the rate of depolarization and overshoot of the action potential of the upper and middle nodal cells.[44] At rest, vagal and sympathetic tone are evenly balanced[45,46]; hence, the ventricular rate usually oscillates within limited boundaries. However, any stimulus such as stress or exertion which leads to either an increase in adrenergic or a decrease in vagal influences will markedly enhance the A-V transmission of atrial impulses. This fact creates a serious problem for the patient with AF.

In normal sinus rhythm, the A-V node acts only as a *delaying* structure (the P-R interval). Sympathetic enhancement of A-V conduction does not per se affect heart rate, since the ventricular rate is a priori determined by the firing frequency of the sinoatrial node (S-A) only, and the latter increases in a manner commensurate with the intensity of sympathetic influences. Therefore, the ventricular rate is directly related to the effect of stress on the firing frequency of the S-A node and is not affected by autonomic-induced changes in A-V nodal conduction. In AF, where the A-V node is constantly bombarded by 600 impulses every minute, A-V nodal conductivity becomes the only regulating mechanism capable of controlling the ventricular rate. Although the A-V node functions well as a *delaying* structure, it is not effective as a *filter* of excessive atrial activity, especially in the presence of the increased sympathetic and decreased vagal tone associated with stress and exercise. Enhanced A-V nodal conduction in these conditions, therefore, results in excessive impulse transmission and disproportionately high ventricular rates, far beyond the "normal" and expected acceleration produced by similar stress in the presence of sinoatrial rhythm.

Digitalis slows conduction across the A-V junction and prolongs the effective refractory period at concentrations that do not otherwise modify the nodal action potential.[47] This change is the result of the cholinergic and antiadrenergic actions of digitalis[48] and is greatly attenuated by the vagolytic action of atropine or by exercise.[49] Although studies in transplanted denervated human hearts indicate that digitalis may exert direct actions on A-V conduction,[50] these actions appear small in magnitude compared with the role of the autonomic nervous system in mediating the drug's effects.[48,50,51] This explains the minimal effect of digitalis on the ventricular response in AF during stress and exertion, states accompanied by a withdrawal of vagal tone and by a marked increase in adrenergic activity[46]; these forces serve to abolish the indirect effects of digitalis and override whatever direct actions the drug may exert on the A-V junction. The inevitable result is a marked increase in the number of impulses conducted through the A-V junction.[52]

Verapamil in the Management of AF

Mechanism of action of verapamil: In addition to its possible effects on atrial impulses, verapamil depresses the amplitude of action potentials in the upper and middle regions of A-V node and lengthens the time-dependent A-V nodal refractory period[53–56]; the drug's actions on the amplitude of middle A-V nodal action potentials are *more* pronounced at rapid than at slow atrial stimulation rates.[53] These effects of verapamil are due to its *direct* blocking properties on the slow ionic channels of the A-V node[53–56] and are not mediated by the cholinergic or adrenergic nervous systems.[54–57] Thus, verapamil (but not digitalis) continues to exert its direct effects during exercise.

Intravenous verapamil in AF: The blocking properties of verapamil on the *human* A-V node in atrial fibrillation were first discovered in 1965 by Bender et al.[58] In 156 cases of AF, these investigators achieved a 24% decrease in the mean ventricular rate with a 5 to 15 mg dose of intravenous verapamil.[59] Numerous reports subsequently confirmed the prompt, effective, and relatively safe control of the ventricular rate with intravenous verapamil in patients with acute and chronic AF of various causes, including that associated with acute myocardial infarction.[60–72]

The acute effects of verapamil are particularly important in the *fully digitalized* patient with uncontrolled AF, to whom the administration of additional doses of digoxin is avoided because of fears of digitalis toxicity. Not all patients respond to verapamil, however. Schamroth[73] observed significant slowing of the ventricular rate in 78% of 1,474 episodes of AF; the faster the rate before therapy, the greater the reduction in rate after administration of verapamil. The observation that the magnitude of the response depends on the rapidity of the pretreatment ventricular rate is similar to the experimental findings of Wit and Cranefield[53] in the A-V node of the rabbit. Patients with very high ventricular rates associated with acute congestive heart failure, however, may not respond even to high doses (and plasma levels) of verapamil.[70]

AF in the Wolff-Parkinson-White syndrome: In this entity, atrial impulses may be propagated to the ventricles through the A-V node, through the accessory pathway, or by both mechanisms. Since verapamil has little effect on the fast sodium channels, it has little effect on the accessory pathway itself,[74] since the latter is composed of ordinary myocardial cells; however, verapamil may accelerate the ventricular response in patients with AF associated with preexcitation syndromes by a variety of mechanisms.[69,71,74] Verapamil can shorten the refractory period of the accessory pathway in some patients[74]; furthermore, the increased block at the A-V node induced by the drug may enhance antegrade conduction through the accessory pathway indirectly by decreasing the number of available abortive impulses attempting to pass retrogradely through the accessory pathway[69,71]; this also may occur with digitalis.[75] Lastly, the increased sympathetic tone resulting from the decrease in systemic vascular resistance

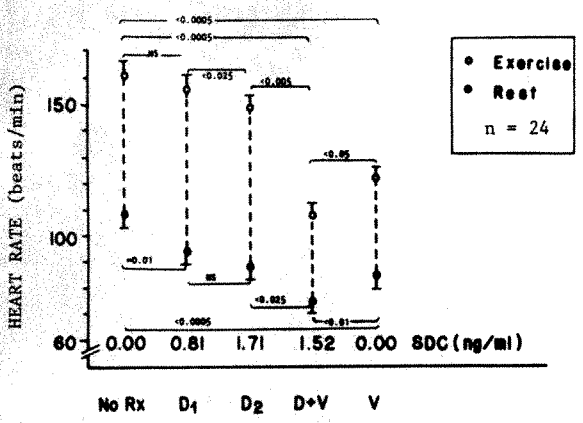

FIGURE 1. Ventricular rate of 24 patients with chronic atrial fibrillation at rest and after mild exercise (300 kpm for 3 minutes) before therapy (No Rx); during treatment with digoxin, 0.25 mg daily (D_1) or 0.50 mg daily (D_2); during combined therapy of digoxin, 0.25 mg, and verapamil, 240 mg daily (D + V); and during treatment with verapamil, 240 mg daily (V). The p value was <0.001 for the entire comparison analyzed by one-way analysis of variance for multiple comparisons; p values are also shown for comparison among treatment phases. SDC = mean serum digoxin concentration during each treatment.

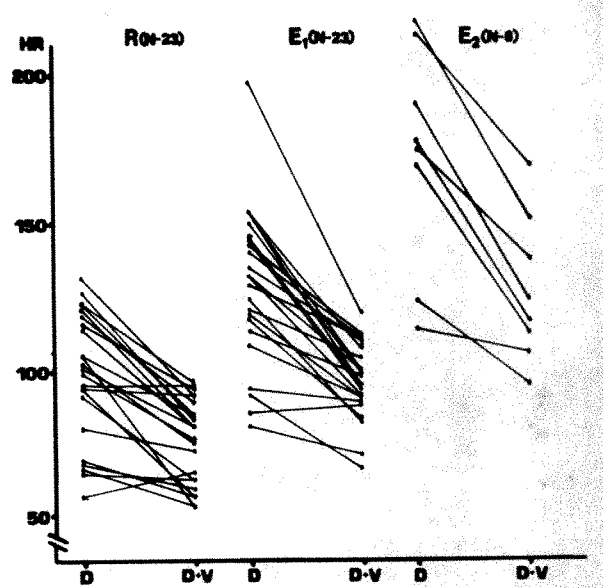

FIGURE 2. Heart rate of 23 digitalized patients with chronic atrial fibrillation before and after the addition of 160 to 240 mg of verapamil daily; ventricular responses were assessed at rest, during mild exercise (E_1: 300 kpm for 3 minutes), and in 8 patients after moderate exercise (E_2: an additional 3 minutes at 600 kpm). D = digoxin therapy only; D + V = digoxin combined with verapamil. (Adapted from Reference 78, with permission.)

after intravenous administration of verapamil could facilitate the transmission of impulses across the accessory pathway.[71] Petri et al.[76] recently showed that verapamil decreased the ventricular rate in patients with the Wolff-Parkinson-White syndrome if most of the impulses were propagated across the A-V node, whereas it *increased* the ventricular response if most of the impulses were conducted across the accessory pathway; however, the number of beats conducted via the accessory pathway was increased after the administration of verapamil in *both* groups of patients. Verapamil is not recommended to control the ventricular rate in patients with AF associated with preexcitation syndromes, in whom conduction occurs primarily by the accessory pathway.

Effectiveness of oral verapamil in AF: Although early doubts were expressed concerning the efficacy of *oral* verapamil in patients with supraventricular tachycardia and AF,[59,62,77] these fears have proved unfounded, if sufficiently large doses of the drug were administered to overcome the extensive hepatic metabolism of the drug. We conducted a series of clinical investigations to evaluate the role of oral verapamil (either alone or in combination with digitalis) in the management of patients with chronic AF.[24,78,79] In the first study, the ventricular response at rest and during two levels of exercise was evaluated in 23 digitalized patients with chronic AF before and after the addition of 160 to 240 mg of verapamil daily. Mean resting heart rate decreased from 99 ± 23 (mean ± standard deviation) to 76 ± 15 beats/min (p <0.001) after the addition of verapamil; the drug also reduced heart rate during mild exercise (300 kpm for 3 minutes) from 128 ± 24 to 96 ± 13 beats/min (p <0.001), and during moderate exercise (600 kpm for 3 minutes) from 173 ± 38 to 127 ± 20 beats/min (p <0.01) (Fig. 2).[78] In a fashion similar to that of previous investigators,[53,73] the effect of oral verapamil on the resting ventricular rate was more marked in the patients with higher pretreatment heart rates than those with lower rates of response.

Following the encouraging results obtained with the combination of verapamil and digoxin, we investigated the effectiveness of verapamil as the *only* therapeutic agent in chronic AF.[24] We compared the ventricular responses at rest and during exercise in 24 patients with chronic AF during five treatment periods: (1) on no treatment, (2) on oral verapamil *alone* (240 mg daily), (3) and (4) on two dose levels of digoxin therapy (0.25 and 0.5 mg daily), and (5) on the combination of digoxin 0.25 mg daily plus verapamil (240 mg daily). As discussed earlier, digoxin was ineffective in controlling the ventricular rate during exercise; in contrast, verapamil *alone* markedly decreased (by 24%) the ventricular response both at rest and during exercise when compared with no treatment (p <0.0005) (Fig. 1). The combination of verapamil and digoxin was more effective than verapamil alone (a reduction in exercise response by 29%), but the magnitude of the additional benefit with the addition of digitalis was small.

Finally, it is important to prove that the reduction in ventricular rate in AF is clinically beneficial.[80] Although therapy with beta-blocking agents causes a marked reduction in the ventricular response at rest and during exercise,[23,81] exercise capacity *deteriorates* in patients treated with propranolol.[81] To determine whether verapamil might produce similar detrimental effects, we evaluated maximal exercise capacity using a multi-

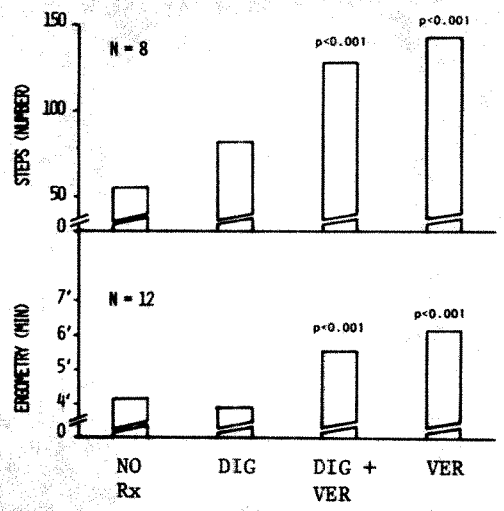

FIGURE 3. Maximal exercise capacity assessed by number of steps on a modified Master test and by the maximal duration of time spent in minutes in a single stage ergometry test in 20 patients with chronic atrial fibrillation receiving either no treatment (NO Rx); digoxin, 0.25 mg alone (DIG); digoxin combined with verapamil (DIG + VER); or verapamil alone (VER).

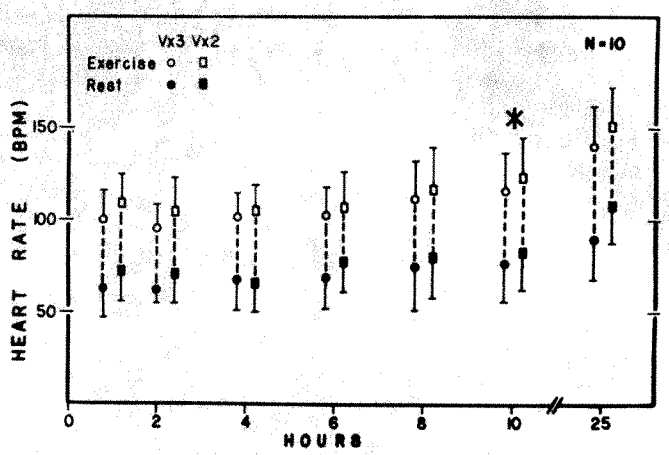

FIGURE 4. Comparison of efficacy of verapamil 80 mg in three daily doses (V × 3) versus 80 mg in two daily doses (V × 2) in 10 digitalized patients with chronic atrial fibrillation. On the day of testing, the patients took their usual morning dose of verapamil only, and the ventricular rate was determined every 1 or 2 hours thereafter, at rest and after a standardized submaximal exercise test. Heart rate remained controlled for more than 8 hours after the administration of verapamil. Ten and 25 hours later there was a significant increase in heart rate, but this occurred similarly with both regimens. The **asterisk** shows the hour in which the increases in rate with both regimens became statistically significant ($p < 0.05$).

stage ergometry exercise protocol in a double-blind, randomized crossover study of 20 patients with chronic AF treated with digitalis.[79] Maximal exercise capacity was scored according to a work capacity formula, where the duration of each stage of exercise was multiplied by the work performed. When the combination of digoxin and verapamil was compared with digoxin alone, maximal exercise capacity was increased 54% by the addition of verapamil (from 522 ± 258 to 806 ± 349 units, $p < 0.001$), while heart rate and systolic blood pressure at the point of maximal exercise were significantly decreased (from 165 ± 28 to 136 ± 29 beats/min, $p < 0.001$, and from 161 ± 89 to 153 ± 86 mm Hg, $p < 0.01$, respectively). In a second group of 20 patients, we compared the maximal number of steps achieved in a modified Master one-step test and the maximal duration of 300 kpm ergometry during no treatment, during treatment with digoxin 0.25 mg daily, verapamil alone (240 mg daily), and a combination of both drugs. The superior control of resting and exercise heart rate with verapamil was associated with improved effort tolerance; the addition of digoxin to verapamil did not produce significant additional benefits compared with those seen with verapamil alone (Fig. 3).

The patients in our studies have either felt better or unchanged after the institution of verapamil therapy. No serious adverse effects were detected with the doses used. All patients with AF had long-term control of ventricular rates (up to 5 years) similar to that seen during the initial treatment period.

Accordingly, we believe that verapamil is now the treatment of first choice in the management of patients with chronic AF; the doses used range from 160 to 240 mg daily, with the dose titrated according to the results of low level (300 kpm) ergometry. Digitalis therapy is reserved for patients who require and may benefit from its potential inotropic effects. The dosage of verapamil may have to be adjusted periodically. For example, the evening dose may be omitted in many patients (conversion of 80 mg three times daily to 80 mg twice daily) without a loss of effective rate control (Fig. 4); this adjustment may avoid excessive nocturnal bradycardia. If the rate appears to escape the influence of verapamil,[71] the development of congestive heart failure should be suspected, because heart failure tends to increase the ventricular rate even during therapy with the drug.[70] Although the ventricular response in patients with AF frequently may be regularized by increasing the dose of verapamil,[82] we do not attempt to achieve this effect because a regularized response has not been shown to provide any greater benefit than that achieved by rate control, and the increase in dose is likely to be associated with increased drug toxicity.

Plasma verapamil concentrations: Both intravenous and oral verapamil administration produce a wide range of plasma verapamil concentrations in patients with and without tachyarrhythmia.[70,83,84] Nevertheless, the prolongation of A-V conduction with therapeutic doses of verapamil is dependent on the plasma drug levels achieved in each patient.[85,86] Sung et al.[87] related the time course of plasma verapamil concentrations and its therapeutic effects in two groups of patients, one with inducible supraventricular tachycardia and the other with AF and a rapid ventricular response. Peak levels of verapamil blocked the induction of supraventricular tachycardia and slowed the ventricular response in AF; however, tachycardias could be induced once again 30

to 45 minutes after verapamil administration, when the plasma levels of the drug had decreased to 50% of their peak values. In contrast, slowing of the ventricular rate in the patients with AF lasted much longer (2 to 3 hours), at which time plasma levels of the drug were less than 20% of their peak value. Hence, interruption of a tachycardia circuit and prevention of tachycardia induction appears to require higher verapamil plasma concentrations than does slowing of A-V conduction in AF.

Our results with oral verapamil confirm the observations of Sung et al.[87] We related plasma concentrations of the drug to the rapidity of the ventricular response with chronic AF in 10 patients who received 80 mg of verapamil twice daily. The maximal decrease in ventricular response was observed at peak plasma drug levels (158 ± 83 ng/ml), but heart rate was still effectively controlled 8 hours after drug administration, when plasma concentrations had declined to 62 ± 28 ng/ml, a concentration substantially below the effective drug concentration for preventing the induction of supraventricular tachycardia.[83]

The role of plasma verapamil determinations in the clinical management of AF is unclear. Dominic et al.[70] found a poor correlation between rate response and plasma drug levels. Other factors, such as high circulating catecholamines, drug interactions, the degree of binding of verapamil by the A-V node, and the presence of biologically active metabolites are likely to influence the pharmacodynamic actions of verapamil in AF; all these factors likely account for the poor relationship between plasma drug levels and response. The finding of a low plasma verapamil level in a patient with apparently refractory AF or, vice versa, a very high plasma concentration in a patient with a profound reduction in ventricular rate is likely to be helpful in determining the optimal dose of verapamil to be used.

Interaction of Digitalis and Verapamil

Effects of Verapamil on Serum Digoxin Concentrations

Several drugs have recently been shown to influence the metabolism and disposition of digoxin,[88–91] but most have not proved important clinically. The first evidence that digoxin drug interactions were clinically relevant was provided by reports that quinidine increased serum digoxin concentration and could cause digitalis toxicity.[92–95] These reports suggested the possibility that a similar interaction might be occurring with digoxin and verapamil in patients receiving both drugs for chronic AF.

We conducted two studies to investigate a possible interaction. In the first, serum digoxin concentrations were determined in 49 patients with chronic AF receiving a daily dose of 0.25 mg of digoxin before and 2 weeks after the addition of oral verapamil, 240 mg daily.[96] Verapamil increased the mean serum digoxin concentration by 70% (from 0.76 ± 0.35 to 1.31 ± 0.54 ng/ml, p <0.0005). Verapamil also increased the serum digoxin concentration in 5 patients with atrial fibrillation receiving 0.50 mg daily of digoxin (from 1.39 ± 0.46 to 2.51 ± 0.80 ng/ml, p <0.05).[96] In the second study, which was conducted as part of the double-blind crossover evaluation of verapamil on exercise capacity in 29 patients,[79] mean serum digoxin concentrations rose by 65% after the addition of verapamil. Similar increases in serum digoxin concentration after the addition of verapamil have been observed by others.[97,98]

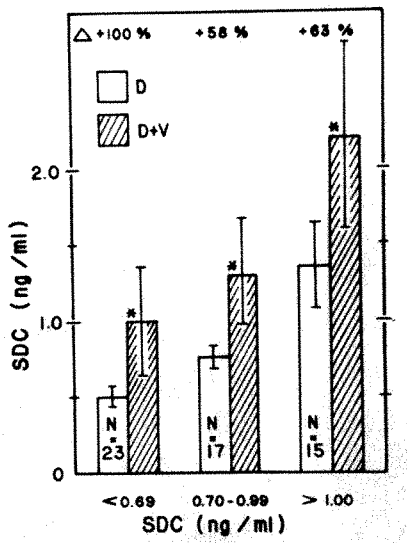

FIGURE 5. The mean serum digoxin concentration (SDC) before and after the addition of verapamil on the **ordinate**, plotted against the original mean serum digoxin concentration during treatment with digoxin alone on the **abscissa.** SDC increased uniformly in all 3 subgroups of patients. Δ% = percent change in serum digoxin concentration. N = number of patients in each subgroup. **Lines** represent 1 standard deviation. **Asterisks** indicate p <0.05.

Our original study[96] demonstrated the additional following characteristics of the digoxin-verapamil interaction: (1) It occurs at all levels of digitalization (Fig. 5). (2) It is time-dependent; the serum digoxin concentration increases gradually and linearly during the first few days of verapamil therapy, reaches 90% of the peak values by 7 days, and peak values by 14 days. (3) It is dose-dependent; the serum digoxin concentration is increased more by 240 mg daily of verapamil than by 160 mg daily of the drug (0.60 ± 0.11 ng/ml before verapamil, 0.84 ± 0.18 with 160 mg of verapamil daily, and 1.24 ± 0.4 ng/ml with 240 mg of verapamil daily, p <0.01). (4) The serum digoxin concentration remains elevated throughout the day, and thus truly represents a new steady state induced by verapamil.

Mechanisms Underlying the Interaction of Digoxin and Verapamil

To define the mechanisms by which verapamil increases serum digoxin concentration, we determined renal digoxin clearance before and during therapy with verapamil in 3 normal volunteers and 7 patients with AF.[96] Renal clearance fell by 40 to 53%, while the serum digoxin concentration rose by about 40% (Fig. 6); one

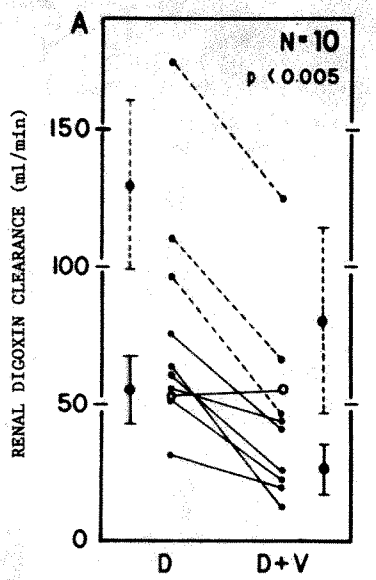

FIGURE 6. Individual and mean renal digoxin clearance in 7 patients with chronic atrial fibrillation (**solid lines**) and 3 normal volunteers (**dashed lines**). Digoxin clearance decreased from 55 ± 12 to 26 ± 10 ml/min ($p < 0.005$) in 6 patients and remained unchanged in the single patient (shown by the **open circles**) in whom serum digoxin concentration failed to increase. Digoxin clearance also decreased from 129 ± 33 to 79 ± 35 ml/min ($p < 0.005$) in the 3 normal volunteers. D = digoxin; D + V = digoxin and verapamil. (Adapted from Reference 96, with permission.)

patient had no significant change in either serum digoxin concentration or renal digoxin clearance. Thus, the increase in serum digoxin concentration can be explained in part by a decrease in renal clearance of the drug. Since glomerular filtration was not affected by verapamil in these 10 patients, the decrease in renal clearance of digoxin is likely due to a decreased tubular secretion of the drug, an effect similar to that described by quinidine.[95] Other investigators recently showed that both the metabolic (nonrenal) clearance and the volume of distribution of digoxin is decreased by verapamil, in addition to the decrease in renal digoxin clearance.[84,98]

The ultimate biochemical mechanism and sites of action of the interaction remains to be clarified. Nifedipine also increases serum digoxin concentration,[97] suggesting that the renal tubular secretion of digoxin may be mediated by slow channel-dependent mechanisms.

Clinical Implications

The clinical implications of the interaction between verapamil and digoxin are unclear. By increasing the availability of digoxin to brain or cardiac tissue, verapamil could theoretically provoke digitalis toxicity, in a fashion similar to quinidine.[99,100] Verapamil could either detract from the positive inotropic effect of digoxin by displacing digoxin from cardiac binding sites (as has also been suggested for quinidine),[101,102] or may enhance its inotropic effect by increasing circulating drug levels.[103] Of our original 49 patients,[96] 7 (14%) had symptoms and electrocardiographic findings compatible with mild to moderate digitalis intoxication, and serum digoxin concentrations exceeded 1.9 ng/ml in 5 of these 7 patients. In the 6th patient, the plasma level of digoxin was only 1.4 ng/ml, but this was measured 60 hours after the last dose of digoxin. In the seventh patient, A-V junctional rhythm was present with a serum digoxin concentration of 0.88 ng/ml; this probably represented the additive effects of digoxin and verapamil rather than an effect mediated by an increase in serum concentration of digoxin. In our second study of 29 patients, only one patient (3.4%) had serious digitalis toxicity.

Based on our observations, we estimate the risk of developing digitalis toxicity in a large population receiving 240 mg daily of verapamil at approximately 10%. This percentage could be higher if larger doses of verapamil are used. Whether verapamil increases or decreases the inotropic effects of digoxin on the heart, however, remains unclear.

The interaction between verapamil and digoxin does not mitigate against the use of both drugs in combination. Most patients with normal renal function receiving 0.25 mg of digoxin daily are underdigitalized, and thus the interaction may actually result in more adequate digitalization. In view of the low toxic to therapeutic ratio of digoxin, it is evident that caution should be exercised when verapamil is administered to fully digitalized patients. Until further studies are completed, we recommend decreasing the dose of digoxin by one third to one half, followed by determination of the serum digoxin concentration at appropriate intervals. The problem is simplified in the patient with AF because the ventricular response may serve as an adequate indicator of the efficacy of the combined use of digoxin and verapamil.

Hemodynamic and Clinical Effects of Combined Verapamil And Propranolol Therapy in Angina Pectoris

MILTON PACKER, MD, MARTIN B. LEON, MD, ROBERT O. BONOW, MD, JOSHUA KIEVAL, MD, DOUGLAS R. ROSING, MD, and V. BALA SUBRAMANIAN, MD

Because of their common negative chronotropic and inotropic effects, combined therapy of beta-adrenergic blocking drugs and calcium channel antagonists has long been feared to produce synergistic cardiodepressant effects. To evaluate whether such fears are justified when such therapy is used in patients with angina pectoris, five hemodynamic and clinical studies were reviewed. These studies indicated that in patients with preserved ventricular function treated with low or moderate doses of propranolol, verapamil produced little change in cardiac performance; this finding was not significantly different from the effects of verapamil in the absence of beta-blockade. In patients receiving large doses of propranolol, verapamil produced modest but significant cardiodepressant effects; these could be avoided by withdrawal of propranolol for 24 hours. Adverse reactions, when they occurred, were primarily hemodynamic rather than electrophysiologic.

Short-term (48 hours) and long-term (4 weeks) randomized controlled trials, which objectively evaluated exercise tolerance in patients with angina pectoris, demonstrated that combined therapy of verapamil and propranolol was superior not only to placebo but also to either drug alone. In patients with preserved left ventricular function, the incidence of adverse effects with combined therapy was small (less than 10%) but increased to 25% in patients with poor left ventricular performance (ejection fraction less than 30%). Combined therapy of nifedipine and propranolol also produced adverse hemodynamic and clinical reactions.

Combined therapy of beta-adrenergic and calcium channel antagonists can provide substantial clinical benefits for patients with angina pectoris who remain symptomatic with either agent used alone. Because adverse effects can occur, however, patients being considered for such treatment need to be carefully selected and observed.

Verapamil is of established value in the treatment of a wide variety of cardiovascular disorders.[1–4] By inhibiting slow channel activity and thereby blocking the entry of calcium into cardiac muscle cells, the drug exerts direct negative inotropic and chronotropic effects and slows atrioventricular conduction in isolated heart preparations.[5,6] Beta-adrenergic receptor antagonists produce similar hemodynamic effects, possibly because of interference with *intra*cellular calcium transport across the sarcoplasmic reticulum.[7,8] Therefore, it is not surprising that investigators have long suspected that additive cardiodepressant effects might accompany combined therapy with these two drugs because of their ability to inhibit, by different mechanisms, calcium transport to active sites within cardiac contractile elements.[9,10]

Early pharmacologic studies in dogs confirmed the existence of a cardiocirculatory interaction between verapamil and beta-adrenergic antagonists.[11–13] When verapamil alone was administered in these canine experiments, the drug produced marked peripheral vasodilation by its inhibition of calcium influx in vascular smooth muscle; the decrease in peripheral resistance stimulated reflex increases in heart rate and cardiac output, despite direct negative inotropic actions of the drug on the myocardium. In contrast, when verapamil was readministered to dogs after pretreat-

ment with propranolol, cardiac output and heart rate failed to increase; furthermore, significant decreases in myocardial contractile force and increases in ventricular filling pressures were frequently observed.[11–13]

Because of the similar cardiovascular effects and the hemodynamic interactions noted in animal studies, combined verapamil and propranolol therapy has been feared to produce adverse clinical reactions in patients with heart disease.[9] These concerns were supported by clinical case reports of hypotension, atrioventricular block, and asystole after the administration of verapamil to patients receiving beta-adrenergic blocking drugs.[9,14–22] These events were largely observed, however, after the administration of verapamil intravenously to acutely ill patients with supraventricular tachyarrhythmias, many of whom also had congestive heart failure. Severe hypotension, heart block, and asystole have not been reported during combined therapy in patients with coronary artery disease receiving verapamil for angina pectoris. Furthermore, although the immediacy of reported episodes of hypotension, heart block, and asystole to the administration of intravenous verapamil left little doubt as to the causative role of calcium channel blockade in these adverse reactions, the importance of concomitant therapy with beta-adrenergic antagonists was unclear, because similar adverse events can occur after the administration of verapamil alone.[9,17,23–27]

To establish the nature and clinical relevance of the interaction between verapamil and beta-adrenergic antagonists in patients with nondysrhythmic disorders, we reviewed a series of clinical investigations to determine the clinical utility and safety of combined therapy in such patients.

Effects of Verapamil in the Absence of Beta-Blockade

The hemodynamic responses to verapamil are the net result of two interacting forces: its direct negative inotropic and chronotropic effects and its peripheral vasodilator actions[28,29]; the latter not only reduce ventricular afterload,[30] but also stimulate beta-adrenergic reflexes,[12,28,29,31] both of which serve to counteract the direct cardiodepressant effects of the drug. Therefore, the responses to verapamil are determined by the dose of verapamil administered (because the depressant effects of the drug are dose-dependent[6,11,12,29,32]) and the integrity of beta-adrenergic reflex responses. With small doses of verapamil, increases in cardiac output and heart rate occur regularly in response to peripheral vasodilation, because reflex beta-adrenergic stimulation overcomes the negative inotropic and chronotropic effects of the drug; this effect is commonly observed after verapamil administration in animals.[11,12] With larger doses of the drug, no change or small decreases in ventricular performance are observed, as reflex responses are offset by the depressant effects of verapamil[32]; this finding accounts for the effects of the drug in human beings. In patients not receiving other cardioactive drugs, verapamil decreases systemic vascular resistance without consistent improvements in cardiac output associated with decreases in mean systemic arterial pressure without increases in heart rate; furthermore, left ventricular dP/dt max may decrease and right and left ventricular filling pressures may increase, reflecting verapamil's negative inotropic effects.[30–36] With very large doses of the drug beyond the therapeutic range, contractile force and heart rate decrease markedly despite concomitant decreases in systemic vascular resistance, as sympathetic responses are overwhelmed by direct effects of the drug on the myocardium.[32,37,38] Clinicians have long feared that such deleterious circulatory responses might occur with smaller doses of verapamil (within the therapeutic range) if beta-adrenergic reflexes were pharmacologically attenuated.

Hemodynamic Studies of Combined Therapy

Effects of verapamil in patients receiving small doses of propranolol: To determine the hemodynamic effects of combined verapamil-propranolol therapy in patients receiving small doses of beta-adrenergic antagonists, Kieval et al.[39] evaluated 20 patients with chronic stable angina pectoris during diagnostic cardiac catheterization. All patients were treated with oral propranolol in doses ranging from 40 to 480 mg daily (mean 160 ± 92 mg). After right- and left-sided cardiac catheterization and contrast left ventricular angiography were performed and a stable control period was achieved, all patients received verapamil intravenously, initially as a bolus of 0.025 to 0.100 mg/kg and subsequently as a continuous infusion of 0.005 mg/kg/min of the drug for 45 minutes. Hemodynamic and cineangiographic variables were measured again at the end of the infusion period. The left ventricular ejection fraction ranged from 43 to 79%.

Verapamil produced significant decreases in mean arterial pressure and systemic vascular resistance without changes in heart rate, cardiac output, right and left ventricular diastolic pressure or left ventricular systolic and diastolic volume, and ejection fraction (Fig. 1). Heart rate remained unchanged despite the decline in systemic blood pressure; cardiac output and left ventricular ejection fraction did not increase despite a significant decrease in systemic vascular resistance. The mean plasma level of verapamil in this study was 161.8 ± 21.5 ng/ml and the mean plasma level of propranolol was 65.7 ± 13.9 ng/ml.

Six of the 20 study patients experienced notable decreases in systemic blood pressure (below 90 mm Hg systolic in 2 patients), but all of these episodes were asymptomatic. No patient experienced signs or symptoms of congestive heart failure or evidence of advanced atrioventricular block. Kieval et al.[39] concluded that the administration of verapamil to patients receiving small doses of propranolol produces no significant negative inotropic and chronotropic effects.

The effects of verapamil noted by Kieval and associates differ from those observed by Ferlinz et al.[30] in

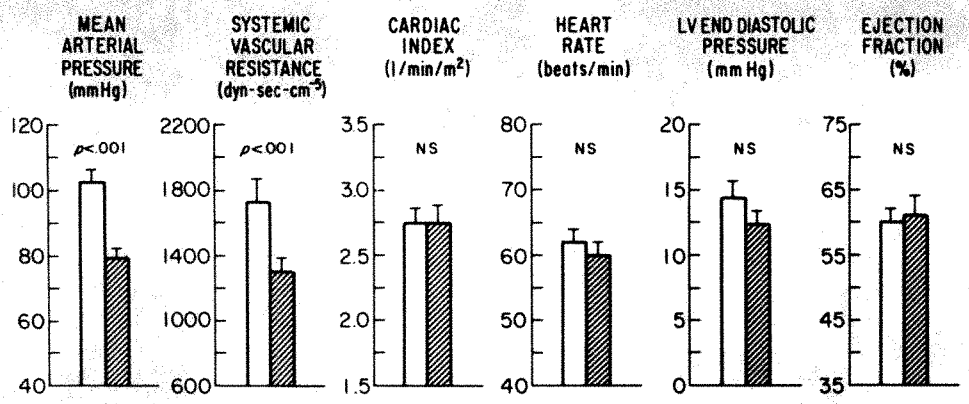

FIGURE 1. Values for mean arterial pressure, systemic vascular resistance, cardiac index, heart rate, left ventricular (LV) end-diastolic pressure, and ejection fraction before (**clear bars**) and after (**shaded bars**) the administration of verapamil intravenously to patients receiving small doses of propranolol (mean 160 mg daily). Significance of differences are shown by the p values **above the bars**. Group data are expressed as mean ± standard error of the mean (SEM). NS = not significant.

patients with coronary artery disease not receiving propranolol. Using a similar protocol in 20 patients undergoing diagnostic cardiac catheterization, Ferlinz and associates found that cardiac output and ejection fraction *increased* in association with drug-induced declines in peripheral resistance, and the decreases in mean arterial pressure were only half as great as those Kieval and associates had observed when the drug was administered with propranolol.[39] Accordingly, Kieval et al.[39] suspected that concomitant therapy with propranolol prevented the improvement in cardiac performance that was expected to accompany the peripheral vasodilator effects of verapamil.

It is unclear whether the lack of improvement in cardiac performance observed by Kieval et al.[39] was the result of concomitant propranolol therapy or the direct cardiodepressant effects of verapamil itself, largely because the findings of Ferlinz et al.[30] differ from those of other investigators who evaluated the effects of verapamil alone in patients with and without heart disease. Singh and Roche,[33] Atterhog and Ekelund,[34] Lewis et al.,[35] and Kellett et al.[36] noted little change in cardiac output, stroke volume, or ejection fraction after verapamil alone despite significant decreases in systemic vascular resistance; such findings are similar to those observed by Kieval et al.[39] in patients receiving concomitant therapy with propranolol. Furthermore, in these four studies, verapamil alone induced significant decreases in left ventricular dP/dt max and increases in right and left ventricular filling pressures.[33–36] The weight of the evidence, therefore, suggests that concomitant therapy with small doses of propranolol does not add significantly to the direct negative inotropic effects of intravenous verapamil alone in patients with preserved left ventricular function.

Effects of verapamil in patients receiving moderate doses of propranolol: To evaluate this interaction further, Leon et al.[40] investigated the effects of combined verapamil-propranolol therapy in patients receiving somewhat larger doses of propranolol. Eleven patients with stable angina of effort not satisfactorily controlled by propranolol alone were evaluated in a randomized triple cross-over study that compared the effects of placebo, propranolol, and verapamil followed by combined verapamil and propranolol. The doses of propranolol alone and in combination with verapamil were 160 to 320 mg daily (mean 255 mg); these doses had previously been individually titrated so as to produce optimal clinical responses without adverse effects, and all patients had resting heart rates less than 60 beats/min. The dose of verapamil used alone and in combination with propranolol was 480 mg daily orally except in 3 patients who received only 320 mg daily during combined therapy with propranolol.

As part of this clinical investigation, Bonow et al.[41] evaluated the effects of placebo, verapamil, propranolol, and combined therapy on left ventricular ejection fraction at rest and during exercise by radionuclide cineangiography before and 48 hours after therapy with each drug regimen. The left ventricular ejection fraction at rest during placebo period averaged 48.4 ± 2.8% (range 32 to 69%) and decreased to 43.4 ± 3.7% ($p < 0.01$) with combined verapamil-propranolol therapy, but these values were similar to those with verapamil alone (43.6 ± 3.6%) (Fig. 2). Five of the 11 patients had a decrease in ejection fraction greater than 5% with verapamil alone; none of them showed any additional decrease during concomitant treatment with propranolol. The ejection fraction during maximal exercise on combined therapy (41.2 ± 2.5%) was similar to that observed during placebo therapy (40.7 ± 3.4%), verapamil alone (41.9 ± 3.4%), or propranolol alone (40.6 ± 2.4%).

Systolic blood pressure at rest measured supine at the time of the radionuclide study decreased from 137.6 ± 7.1 to 117.5 ± 4.6 mm Hg with combined verapamil-propranolol therapy, but these values were similar to those with verapamil alone (120.7 ± 5.4 mm Hg) (Fig. 3). There were no significant decreases in ejection fraction or systolic blood pressure (compared with

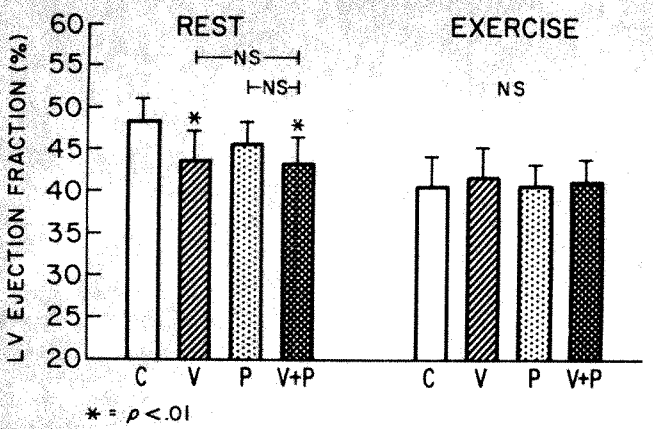

FIGURE 2. Values for left ventricular (LV) ejection fraction during rest and exercise after 48 hours of therapy with placebo (C), verapamil (V), moderately large doses of propranolol (P, mean 255 mg daily), and their combination (V + P) in 11 patients who completed a randomized triple cross-over study. **Asterisks** refer to significance of differences of treatment phases when compared with placebo periods. Values **above the bars** denote significance of differences *between* treatment periods, where NS = not significant. Group data are expressed as mean ± SEM.

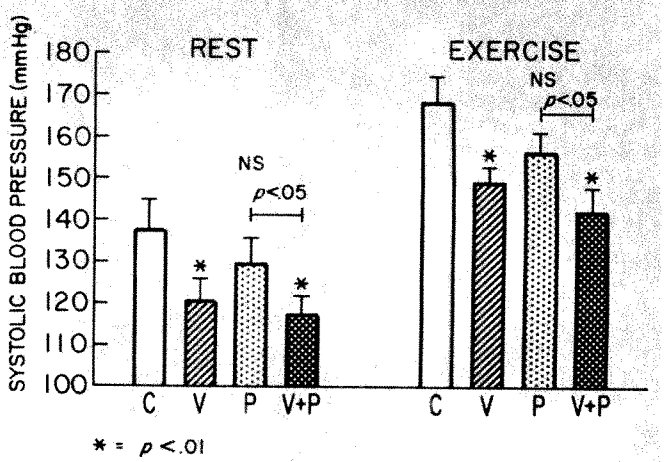

FIGURE 3. Values for systolic blood pressure during rest and exercise in the patients referred to in Figure 2. Format, symbols, and abbreviations as in Figure 2.

placebo) with propranolol alone. The heart rate at rest decreased from 78 to 57 beats/min ($p < 0.01$) with combined therapy, but this was similar to the heart rate during treatment with propranolol alone; verapamil alone produced only mild decreases in heart rate (78 to 71 beats/min, $p < 0.05$).

Of the 11 patients who received combined therapy, 3 had symptomatic adverse reactions. Two patients had orthostatic dizziness, which limited the maximal doses that could be administered. Two patients (1 of whom also had dizziness) had exertional dyspnea; 1 had the lowest pretreatment ejection fraction (32%) of any patient in the study, and 1 had the most marked decrease in ejection fraction (46 to 31%) with verapamil alone with subsequent heart failure during long-term treatment with the drug. Two patients, who experienced atrioventricular dissociation on verapamil alone, never received combined therapy.

The findings of Bonow et al.[41] that combined therapy with verapamil and propranolol produces decreases in ejection fraction and blood pressure similar to those observed with verapamil alone, support the concept that the failure to observe significant improvements in cardiac performance in response to the peripheral vasodilator effects of verapamil is primarily due to verapamil and is not the result of the additive negative inotropic effects of propranolol. This was the finding despite mean propranolol levels in this study (203 ± 33 ng/ml) which were 3 times higher than those observed by Kieval et al.[39]; however, the mean verapamil levels were similar (209 ± 29 ng/ml).

Effects of verapamil in patients receiving large doses of propranolol: To extend these observations to patients taking very large doses of propranolol, Packer et al.[42] evaluated the hemodynamic effects of combined therapy in 15 patients with severe angina at rest. All patients were being treated with large doses of propranolol (160 to 1,280 mg daily, mean 502 mg in 13 patients) or metroprolol (400 mg daily in 2 patients); only 3 of the 13 patients taking propranolol received doses less than 320 mg orally. After right heart catheterization was performed, a stable hemodynamic state was established, and small doses of verapamil were administered to ensure the safety of combined therapy, each patient received single doses of 120 mg of verapamil at 6 to 12 hour intervals; beta-adrenergic antagonists were administered together with the first 120 mg dose of verapamil and then were discontinued. Radionuclide angiographic determinations of left ventricular ejection fraction on propranolol before therapy with verapamil ranged from 35 to 78%.

The first 120 mg dose of verapamil, administered concomitantly with beta-blocking drugs, significantly decreased cardiac index (0.38 liters/min/m^2), stroke volume index (2.8 ml/beat/m^2), heart rate (6 beats/min), and mean arterial pressure (13.2 mm Hg) associated with increases in pulmonary capillary wedge pressure (2.2 mm Hg) and mean right atrial pressure (1.7 mm Hg), all significant at $p < 0.001$ (Fig. 4 and 5); there were no significant changes in systemic vascular resistance. Similar cardiodepressant effects were observed when 120 mg doses of verapamil were readministered 6 hours after beta-blockade withdrawal. The duration of these hemodynamic effects was brief; decreases in cardiac index and heart rate generally persisted only 2 to 3 hours, returning to control values within 4 hours after oral administration. The plasma levels of verapamil after the first administration of 120 mg of the drug were 205.1 ± 40 ng/ml, which were comparable to those noted by Kieval et al.[39] and Bonow et al.,[41] but plasma levels of propranolol were 474.1 ± 84 ng/ml, 2 to 7 times higher than those that characterized patients in these previous studies.

In contrast to the cardiodepressant effects observed when verapamil was administered with beta-blocking drugs, verapamil produced no significant decreases in

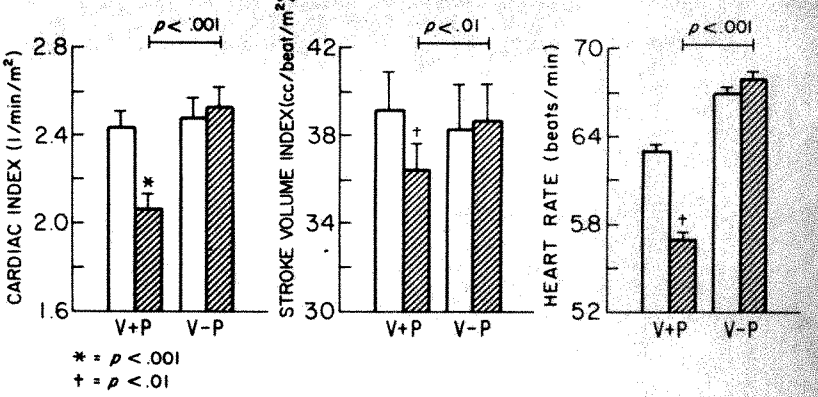

FIGURE 4. Effects of oral verapamil (120 mg) on cardiac index, stroke volume index, and heart rate in 15 patients during therapy with large doses of propranolol (mean dose of 502 mg daily) or metoprolol (400 mg daily), both denoted by V + P, and in the same patients again 30 hours after beta-blockade withdrawal, denoted by V−P. Control values before verapamil are shown in **clear bars** and the effects of verapamil are shown in **shaded bars.** **Symbols** denote significance of effects seen after verapamil compared with their respective controls. p values **above the bars** denote significance of differences between the effects of verapamil during treatment with and after withdrawal of beta-blocking drugs. Group data are expressed as mean ± SEM.

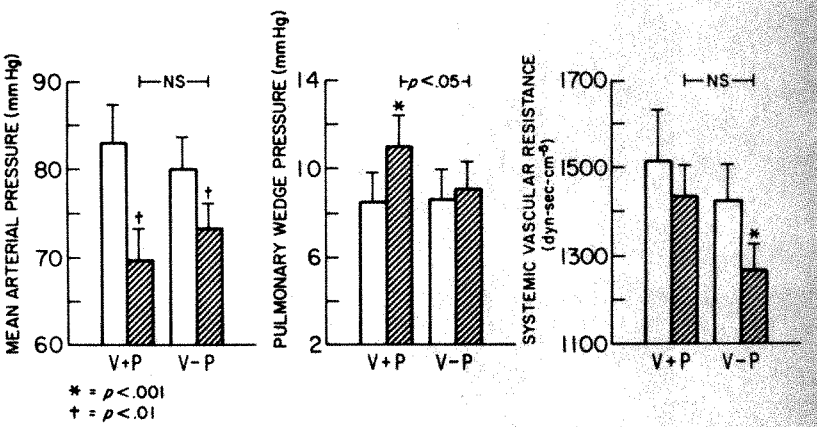

FIGURE 5. Effects of oral verapamil (120 mg) on mean arterial pressure, pulmonary capillary wedge pressure, and systemic vascular resistance in the 15 patients in Figure 4. Format, symbols, and abbreviations as in Figure 4.

cardiac index, stroke volume index, or heart rate and little change in pulmonary capillary wedge and mean right atrial pressures when administered 24 to 30 hours after withdrawal of beta blockade (Fig. 4 and 5). Mean arterial pressure decreased with verapamil not because of a decrease in cardiac output (as during combined therapy) but because of a decline in systemic vascular resistance. These circulatory responses were virtually identical to those noted by Kieval et al.[39] in their patients taking small doses of propranolol; this finding is consistent with the observation that plasma levels of propranolol 24 to 30 hours *after* beta blockade withdrawal in the study by Packer et al.[42] (41 ± 11 to 72 ± 20 ng/ml) were similar to levels seen *during* low dose propranolol therapy in the study by Kieval et al.[39] The progressive decline in the cardiodepressant effects of verapamil (as plasma propranolol levels decreased) was especially remarkable, because plasma *verapamil* levels concomitantly *increased* (from 205 ± 40 to 383 ± 51 ng/ml) with repeated doses of the drug as beta-blocking agents were withdrawn; such higher levels of verapamil would have by themselves been expected to produce *greater* cardiodepressant effects.

Adverse clinical reactions, all of them asymptomatic, were observed in 3 of the 15 patients: 1 patient had transient junctional bradycardia with combined therapy but not with verapamil alone (no additive effects on atrioventricular conduction were noted in the other 14 patients); 2 patients had marked but asymptomatic decreases in mean blood pressure (of 30 and 59 mm Hg) after the first 120 mg dose of the drug, and both had received methyldopa within the past 7 days. In none of the 15 patients did signs or symptoms of congestive heart failure develop during combined drug treatment.

The history of recent methyldopa therapy in the two patients who had hypotensive reactions is of interest. In the intact circulation, verapamil's peripheral vasodilator effects serve to offset its cardiodepressant actions by reflex beta-sympathetic stimulation; thus, only mild hypotension is usually seen with verapamil alone (Fig. 6, top). If beta-adrenergic reflexes are blocked by concomitant propranolol therapy, however, these negative inotropic and chronotropic actions remain unopposed and could combine with the peripheral vasodilator effects of the drug to produce profound hypotension. However, it is likely that the circulation acts to prevent this reaction during combined therapy by reflex *alpha*-sympathetic stimulation which, by producing peripheral arterial and venous vasoconstriction, offsets the direct peripheral vascular effects of the drug (Fig. 6, bottom). This fact explains why verapamil failed to reduce systemic vascular resistance in patients receiving large doses of beta-sympathetic antagonists, but did so after their withdrawal; similar findings were noted in animal models by Rowe et al.[13] This peripheral vaso-

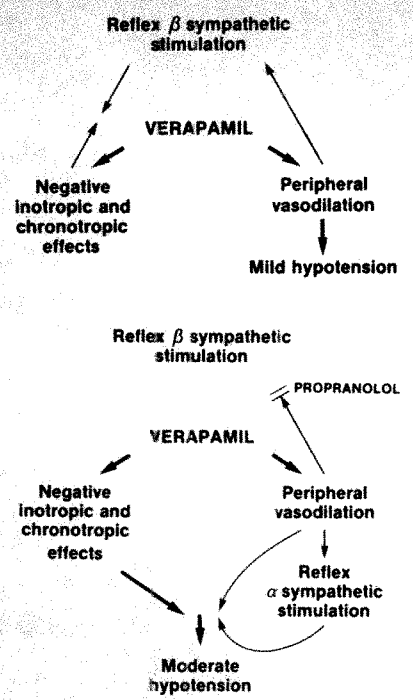

FIGURE 6. Top, diagram showing the effects of verapamil in the absence of beta-blockade. Reflex beta-sympathetic stimulation serves to offset the direct negative inotropic and chronotropic effects of the drug. **Bottom,** diagram showing the effects of verapamil during the administration of beta-adrenergic antagonists. Propranolol blocks beta-sympathetic reflexes and thus leaves the direct cardiodepressant effects of verapamil unopposed. These can summate with the drug's peripheral vasodilator effects and produce profound hypotension unless verapamil's peripheral actions were in turn opposed by activation of alpha-adrenergic reflexes.

constriction probably contributes to the increases in right and left ventricular filling pressures seen with combined therapy but not with verapamil alone. Such observations may account for the marked decreases in blood pressure that may be noted during combined treatment when alpha-sympathetic responses are attenuated as would occur after recent methyldopa or quinidine therapy.[26,43]

Conclusions of hemodynamic studies: The combined experience from the three foregoing clinical studies leads us to the following conclusions. In patients with preserved left ventricular function, verapamil produces little change in cardiac performance in most patients with coronary artery disease not receiving beta-receptor antagonists; however, significant decreases in ejection fraction (more than 5%) may occasionally be seen and may result in clinical congestive heart failure. Verapamil produces little change or mild decreases in cardiac performance in patients receiving small doses of propranolol; these hemodynamic effects probably do not differ from those that would be observed in these patients with verapamil alone. Verapamil produces modest but significant cardiodepressant effects in patients taking large doses of propranolol; such deleterious effects can be avoided by withdrawal of propranolol for 24 hours.

Our observations indicate that the magnitude of the adverse interaction between verapamil and propranolol depends greatly on the dose of propranolol administered. This fact suggests that large doses of propranolol are needed to attenuate beta-adrenergic reflexes sufficiently to leave verapamil's negative inotropic effects unopposed. Such a concept conflicts with the work of Chidsey et al.[44] who reported that near maximal beta-blockade is achieved with relatively small doses of propranolol (such as 160 mg daily) and low plasma levels of the drug (75 to 100 ng/ml). However, if this were the case, we would have expected similar cardiodepressant effects of combined therapy in all of our studies; our findings that adverse interactive hemodynamic effects were dose-related could then only be explained by assuming that propranolol exerts negative inotropic effects independent of its effects on beta-adrenergic receptors, which it does not do in clinically relevant doses.[45,46] Rather, our findings are more consistent with the work of Goldstein et al.,[46] Shand,[47] and Coltart and Shand[48] who reported that the degree of beta-adrenergic blockade varies linearly with plasma propranolol concentrations, even up to levels exceeding 500 ng/ml.

Of the 46 patients who received short-term combined therapy in these three studies, there were 13 reactions in 12 patients that were of concern to the investigators. In 10 of these patients, *hypotension* was the adverse effect observed; congestive heart failure was observed in 2 patients and a cardiac conduction abnormality in one. Only 4 episodes in 3 patients (7%) were symptomatic and required a reduction in the dosage of verapamil; none of these was severe enough to require discontinuation of therapy.

The 7% frequency of symptomatic adverse reactions observed in these hemodynamic studies, however, may have underestimated the true frequency of such events. The duration of combined therapy in these studies was brief, and adverse clinical responses may be more frequent during more prolonged treatment. Furthermore, ventricular function in these patients before therapy was generally well preserved (all had an ejection fraction of 30% or greater); Chew et al.[49] have shown that the negative inotropic effects of verapamil may be most evident and precipitation of heart failure most likely in patients whose ejection fractions are less than 30%. The true incidence of adverse reactions with combined therapy can only be determined by careful observation and analysis of a far larger number of patients over longer periods of time.

Clinical Studies of Combined Therapy

Physiologic considerations: There is strong theoretic and clinical support for the use of combined verapamil and propranolol therapy in patients with angina pectoris. Propranolol exerts its effects primarily by its negative chronotropic and inotropic actions.[50] The drug markedly attenuates exercise-induced increments in double-product (primarily by decreasing heart rate) at submaximal and at maximal workloads.[50,51] However,

verapamil exerts its effects by decreasing ventricular afterload consequent to peripheral vasodilation,[52] by antagonizing coronary vasospasm,[3] and by improving diastolic function[41] rather than by primarily decreasing heart rate or contractility. Exercise-induced increments in double-product are attenuated by verapamil at submaximal workloads (primarily by decreasing blood pressure), but increments in double-product at maximal exercise are similar to those achieved before therapy, although at a substantially greater work load.[4,51,53] A combination of the two drugs, acting by different mechanisms, might then be expected to possess additive or synergistic effects on anginal symptoms.

We have already emphasized that the administration of verapamil to patients not receiving propranolol stimulates the beta-adrenergic nervous system, which serves to support circulatory homeostasis by opposing the direct cardiodepressant effects of verapamil. However, this increase in beta-sympathetic activity may detract from verapamil's antianginal actions by increasing heart rate and contractile force.[28] On the other hand, the administration of propranolol to patients not receiving verapamil inhibits beta-adrenergically mediated coronary vasodilation and consequently may exacerbate symptoms in patients in whom vasospasm is playing an important role.[54–56] Combined drug therapy may therefore produce synergistic benefits on anginal symptoms not only because each drug exerts independent antianginal effects but also because each may serve to oppose the concomitant unfavorable cardiovascular actions of the other.

Comparative clinical trials: Two randomized binded clinical trials compared the *effectiveness* of combined therapy with the benefits achieved by treatment with either drug used alone. In the study by Leon et al.,[40] the effects of placebo, propranolol, and verapamil on exercise duration and clinical symptoms were assessed using a randomized triple cross-over design in 11 patients with stable effort angina who remained symptomatic on propranolol alone; all patients had preserved left ventricular function (ejection fraction greater than 30%). The doses of propranolol ranged from 160 to 320 mg daily and had previously been individually titrated so as to produce resting heart rates less than 60 beats/min; the doses of verapamil were 320 to 480 mg daily. Exercise tolerance (evaluated by bicycle ergometry) was assessed under double-blind conditions after each drug had been administered for 48 hours. After the randomized phase of the trial was completed, patients were treated in an open-label fashion with their usual doses of propranolol to which verapamil (320 to 480 mg daily) was added, after which exercise capacity was reevaluated.

The mean duration of exercise was 5.1 ± 0.7 minutes with placebo, 6.5 ± 0.5 minutes with propranolol, and 8.5 ± 0.7 minutes with verapamil (480 mg daily); the differences among all 3 treatment groups were significant (Fig. 7). Patients exercised significantly longer on propranolol ($p < 0.05$) and verapamil ($p < 0.01$) than on placebo; exercise was stopped because of angina in 11

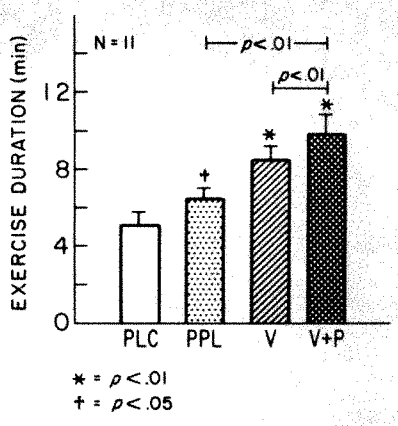

FIGURE 7. Exercise duration in 11 patients with angina of effort after 48 hours of therapy with placebo (PLC), propranolol (PPL), verapamil (V), and combined verapamil and propranolol treatment (V + P) evaluated by a randomized triple cross-over design. **Symbols above the bars** denote significance compared with placebo therapy; **p values above the bars** denote significance between the treatment groups. Group data are expressed as mean ± SEM.

patients on placebo, 9 on propranolol, and 10 on verapamil. When verapamil (mean dose 407 mg daily) was added to propranolol, exercise duration increased to 9.8 ± 1.0 minutes. This duration was significantly better than that with either propranolol alone ($p < 0.01$) or verapamil alone ($p < 0.01$); only 2 of the 11 patients with combined therapy had angina during exercise. The investigators concluded that the addition of verapamil to patients receiving propranolol improved exercise tolerance over that observed with either agent used alone.

Bala Subramanian et al.[57] evaluated the effects of individual and combined verapamil-propranolol therapy in 14 patients with stable effort-related angina pectoris, all of whom had preserved left ventricular function (ejection fraction greater than 30%). Initially, 22 patients entered a 2 week single-blind placebo run-in period; an 8 week double-blind trial followed, consisting of 4 weeks of treatment with either verapamil or propranolol, followed by cross over to the alternate drug for an additional 4 weeks. Fourteen of the 22 patients who still had exertional angina during both of the individual treatment periods then received 4 weeks of treatment with both verapamil and propranolol administered in a single-blind fashion. The dose of propranolol was 120 mg daily and that of verapamil 360 mg daily. Exercise capacity was assessed by the duration of exertion on a treadmill at the end of each of the three 4 week treatment periods. One of the 14 patients failed to complete the trial of combined therapy because congestive heart failure developed.

The mean exercise time for these patients while taking placebo was 4.8 ± 0.2 minutes and increased to 6.8 ± 0.6 minutes with propranolol ($p < 0.01$), to 8.0 ± 0.5 minutes with verapamil ($p < 0.01$), and to 10.1 ± 0.9 minutes with combined verapamil-propranolol therapy ($p < 0.01$); the improvement in exercise tolerance with

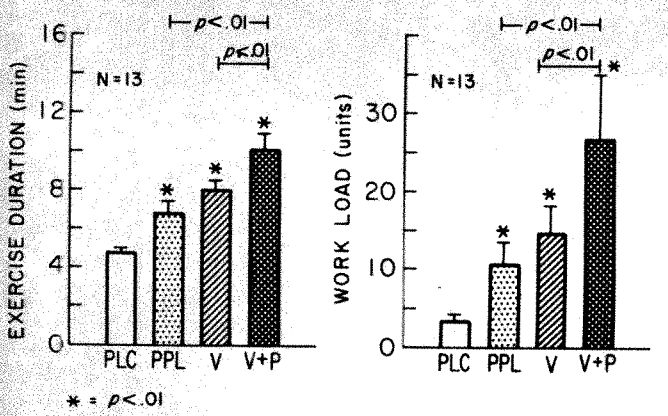

FIGURE 8. Exercise duration and work load achieved in 13 patients with angina of effort after 4 weeks of therapy with placebo (PLC), propranolol (PPL), verapamil (V), and combined verapamil and propranolol treatment (V + P) evaluated by a double-blind randomized cross-over protocol. **Symbols above the bars** denote significance compared with placebo therapy; **p values above the bars** denote significance between the treatment groups. Group data are expressed as mean ± SEM.

combined therapy was superior to that achieved with propranolol or verapamil alone, both $p < 0.01$ (Fig. 8). Because the exercise load was incremental and not linear, work load was calculated by multiplying distance walked in kilometers by the sine angle of treadmill in degrees and expressed in units. The work load achieved with combined therapy (26.7 ± 5.3 units) was substantially greater than that achieved with verapamil alone (14.7 ± 2.1), propranolol alone (10.7 ± 2.6), or placebo (3.5 ± 0.6). Seven of the 13 patients became angina-free with combined therapy. The investigators concluded that combined therapy was superior to either agent alone in patients who remained symptomatic on single-drug therapy.

The findings of both trials must be interpreted in the context of certain precautions and limitations. Patients were generally selected for combined verapamil-propranolol therapy after they remained symptomatic on treatment with either or both drugs alone. Hence, it is unclear whether exercise capacity is enhanced by combined therapy in patients who respond adequately to treatment with a single agent. Furthermore, the trials were conducted such that treatment with verapamil or propranolol alone was double-blinded, but combined therapy was administered under open-label or single-blind conditions; hence, the results might have been affected by both patient and observer bias. Finally, treatment with both drugs always followed therapy with each drug individually, primarily because of fears that combined therapy would produce adverse effects unless it could be shown that each patient tolerated single-agent therapy well. Hence, the greater benefits seen during combined treatment may have been the result in part of a training effect. Leon et al.,[40] however, excluded a training effect in their study.

Most importantly, the beneficial effects of combined verapamil-propranolol therapy in these two studies were observed in patients with preserved left ventricular function (ejection fraction greater than 30%). Bala Subramanian et al.[57] subsequently treated an additional 40 patients with severe exertional angina pectoris with combined therapy, who had severe left ventricular dysfunction (ejection fraction less than 30%). The doses used were verapamil 360 mg daily and propranolol 60 to 120 mg daily. Although many of these patients experienced clinical benefits not seen with either drug alone, adverse effects were observed in 10 of 40 patients (25%). These effects consisted of hypotension in 4 patients, cardiac failure in 3, bradycardia in 1, and a junctional rhythm in 2. These adverse effects were controlled by either discontinuation or reduction in the dose of propranolol. The high incidence of adverse reactions with combined therapy was directly attributable to the more compromised left ventricular function in these 40 patients.

Combined Therapy of Propranolol With Other Calcium Antagonists

The findings of the studies reported in this review apply only to combined therapy with verapamil and not necessarily to other slow calcium channel antagonists such as nifedipine and dilitiazem. Although nifedipine resembles verapamil in depressing slow channel activity in cardiac muscle,[58] it has minimal direct depressant effects on atrioventricular conduction,[32,58–60] and neutralization of its cardiac depressant effects by peripheral vasodilation seems to be more nearly complete with nifedipine than with verapamil[28]; hence, combined therapy with beta-adrenergic antagonists might be safer with nifedipine than with verapamil.

Available data, however, suggest that an adverse interaction also occurs between nifedipine and propranolol in a manner similar to that observed with verapamil and propranolol. Whereas nifedipine alone produces significant increases in ejection fraction, mean circumferential fiber shortening, and peak dP/dt in patients with ischemic heart disease,[61,62] *decreases* in peak dP/dt without change in ejection fraction or mean circumferential fiber shortening are seen after the administration of nifedipine to patients receiving beta-blocking drugs, even those with preserved left ventricular function.[63] Hence, reflex beta-adrenergic stimulation counteracts the intrinsic cardiodepressant effects of nifedipine as it does with verapamil.[28,63,64]

Elucidation of the nature of the hemodynamic interaction between nifedipine and beta-adrenergic antagonists is especially important in view of the increasing number of reports of adverse hemodynamic effects (hypotension and severe congestive heart failure) during nifedipine therapy in patients receiving beta-blocking agents[65–68]; in two reports, symptoms and signs of heart failure disappeared when nifedipine was withdrawn and reappeared when nifedipine was readministered.[65,68] Therefore, caution should be exercised whenever combined therapy of beta-blocking drugs and all calcium antagonists is contemplated.

Although combined nifedipine and propranolol therapy should provide benefits superior to those ob-

served with either drug alone, this result has not yet been confirmed. In the only controlled study that examines this question, Lynch et al.[69] showed that the combination of nifedipine and propranolol was superior to placebo in reducing episodes of angina in a 2 to 4 week double-blind trial; however, combination therapy was not clearly better than propranolol alone. Unfortunately, most patients in the study, as in the verapamil studies, were selected because they remained symptomatic with beta-blocking drug therapy alone. Moreover, the objective criteria of this study consisted only of the magnitude of S-T depression by precordial exercise mapping at a fixed work load and by ambulatory electrocardiographic monitoring; exercise tolerance was not evaluated. Hence, the advantages of combined nifedipine-propranolol therapy in effort-related angina remain unproved.

Hemodynamic and clinical studies of combined therapy of diltiazem and beta-adrenergic antagonists have not yet been reported, so that the safety and effectiveness of this approach is unknown.

Conclusions

Evidence presented in this review indicates that combined verapamil and propranolol therapy is effective in highly selected patients with coronary heart disease. In patients who remain symptomatic despite optimal therapy with propranolol and nitrates, we recommend substitution of verapamil for propranolol, because several well-controlled randomized double-blind trials show that verapamil is superior to propranolol with treatment of angina of effort and at rest.[51,57,70] Available data suggest that such substitution can generally be accomplished safely without the need to withdraw propranolol before instituting verapamil therapy. For patients taking large doses of propranolol, however, the administration of verapamil within 24 hours of the last dose of propranolol can produce significant cardiodepressant effects; therefore, such patients require careful observation of vital signs and cardiac rhythm during the first 24 hours of verapamil therapy, particularly if they have recently been treated with drugs (such as methyldopa or quinidine) that attenuate alpha-adrenergic responses.

In patients who remain significantly symptomatic despite adequate doses of verapamil alone, the addition of propranolol is likely to provide additional therapeutic benefits. Such therapy should be undertaken only in patients with preserved left ventricular function (ejection fraction greater than 30%); propranolol should be initiated in small doses and titrated upwards after careful reevaluation of vital signs and clinical status. In contrast to the present practice of using combined nitrate and beta-blocking drug therapy without the need to prove the effectiveness of either component alone, the experience with combined therapy of calcium antagonists and beta-blocking agents is as yet too limited to recommend its routine clinical use in patients who are responsive to either drug alone.

Until more evidence is available, combined therapy should be avoided or used with great caution after other therapeutic modalities have failed in the following: (1) patients with severe left ventricular dysfunction (ejection fraction of less than 30%); (2) patients with underlying atrioventricular conduction system disease; and (3) patients taking drugs that possess independent negative inotropic effects, such as disopyramide.

Thus, combined calcium channel and beta-adrenergic blockade provides important therapeutic benefits for many patients with severe angina pectoris. Adverse cardiovascular reactions during combined therapy may occur, however, so that more studies are needed to determine the frequency of such reactions and to identify those patients particularly susceptible to an unfavorable response. Until these studies are performed, patients being considered for combined therapy need to be carefully selected and observed.

Acknowledgment

We would like to thank Stephen Epstein, MD, for his helpful constructive review of this manuscript.

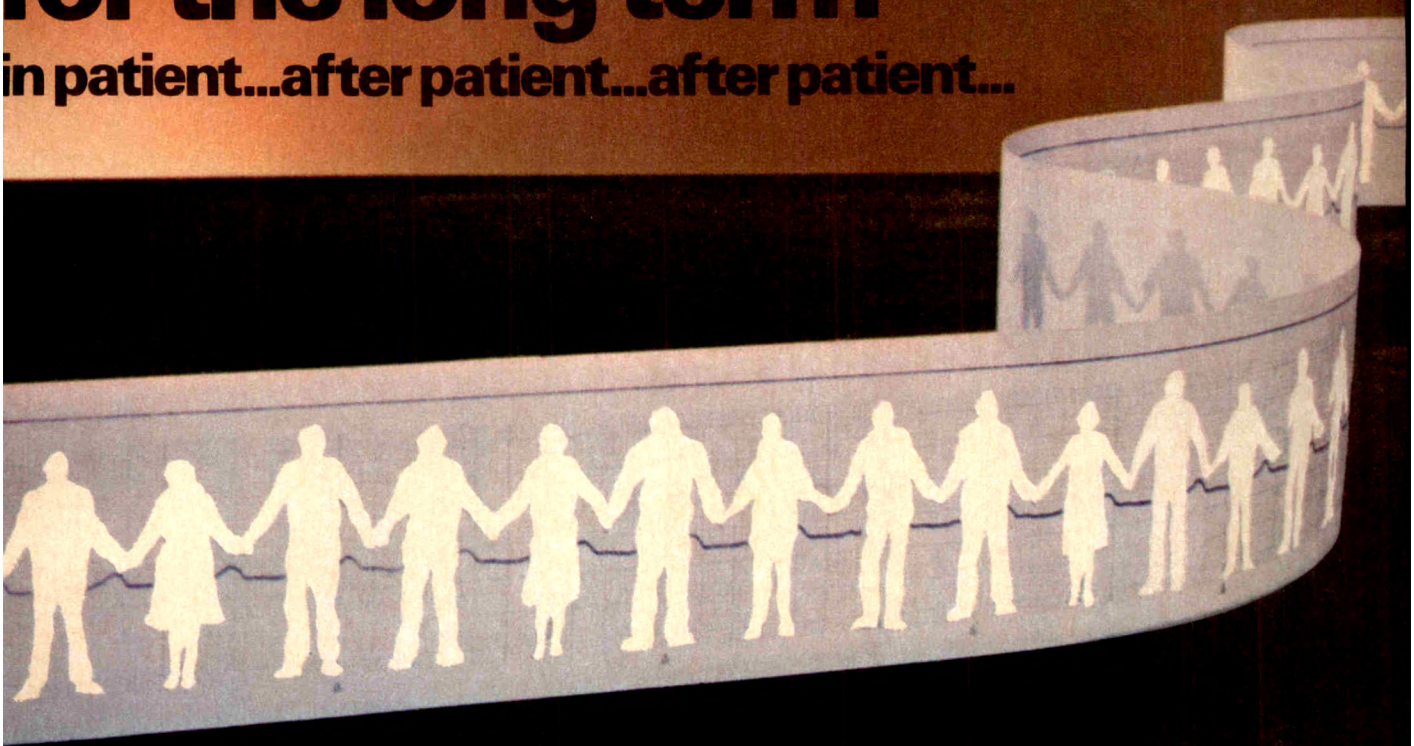
for the long term

in patient...after patient...after patient...



As a consequence of the negative inotropic properties of Norpace, adequate cardiac function must be established and maintained. Norpace should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless secondary to cardiac dysrhythmia. Please see the next page for a brief summary of the complete prescribing information.

- Unsurpassed efficacy in the suppression of ventricular dysrhythmias[1]
- Lower dropout rate than with quinidine[2]
- Side effects most often anticholinergic and dose related
- Does not elevate digoxin serum levels or increase the potential for digitalis toxicity[3]
- Does not induce lupus erythematosus[4]

Norpace®

(disopyramide phosphate)

100-mg and 150-mg capsules

for the long term

Norpace®
(disopyramide phosphate)
100-mg and 150-mg capsules
for the long term

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows: **Indications:** For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin, paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug. **Warnings: Norpace may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.** **Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Antiarrhythmic drugs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced in patients with hyperkalemia. Therefore, potassium abnormalities should be corrected before starting Norpace therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood. **Norpace has been reported to stimulate contractions of the pregnant uterus.** Use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown. Safety and effectiveness of Norpace in children have not been established. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/ triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported. **Dosage and Administration:** Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually with close monitoring. **See current complete prescribing information for dosage recommendations, including pediatric use. How Supplied:** Capsules containing 100 mg or 150 mg of disopyramide base.

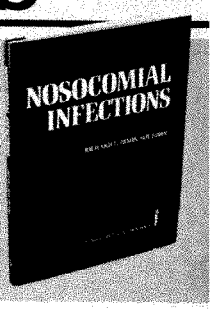
NOSOCOMIAL INFECTIONS

edited by
Richard E. Dixon, M.D.



appx. 344p June 1981,
$29.50 hardbound
ISBN 0-914316-24-9
$19.50 softbound
ISBN 0-914316-29-X

Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, thi book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

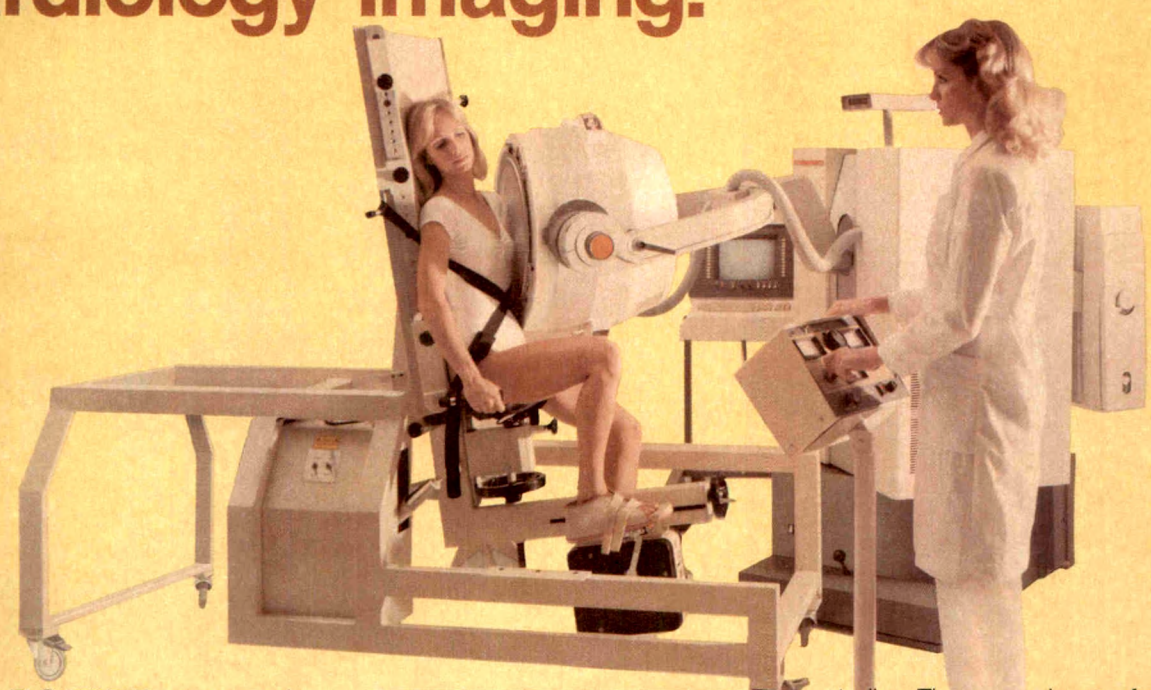
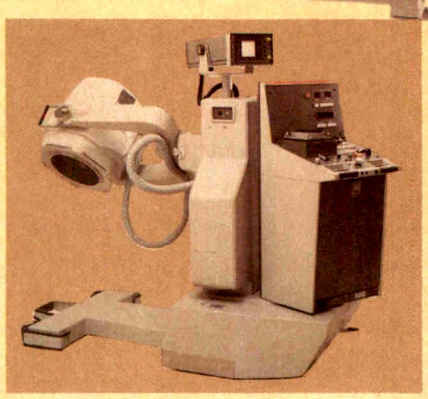
SIEMENS

ZLC and expanded count rate...for reliable nuclear cardiology imaging.



Siemens ZLC 370/750 camera series and lightweight LEM (Low Energy Mobile) system provide you with both the performance and high count rate capability required for dynamic cardiology studies—without loss of image integrity.

The detector arrangement and design of our expanded count rate ZLC 370/750 camera series affords fast and easy patient positioning in demanding stress test examinations. It is also ideally suited for conventional imaging and whole body studies and is easily upgraded for SPECT.



Our LEM system—now featuring ZLC detectors—improves the overall efficiency of bedside cardiology studies. The convenience of a mobile camera is combined with uncompromised image integrity, even in studies demanding expanded count rate.

To maximize your investment, all Siemens systems are offered with comprehensive service programs backed by one of the industry's largest technical service organizations dedicated to nuclear medicine. For additional information on Siemens nuclear imaging systems, contact your local representative or:

Siemens Medical Systems, Inc.

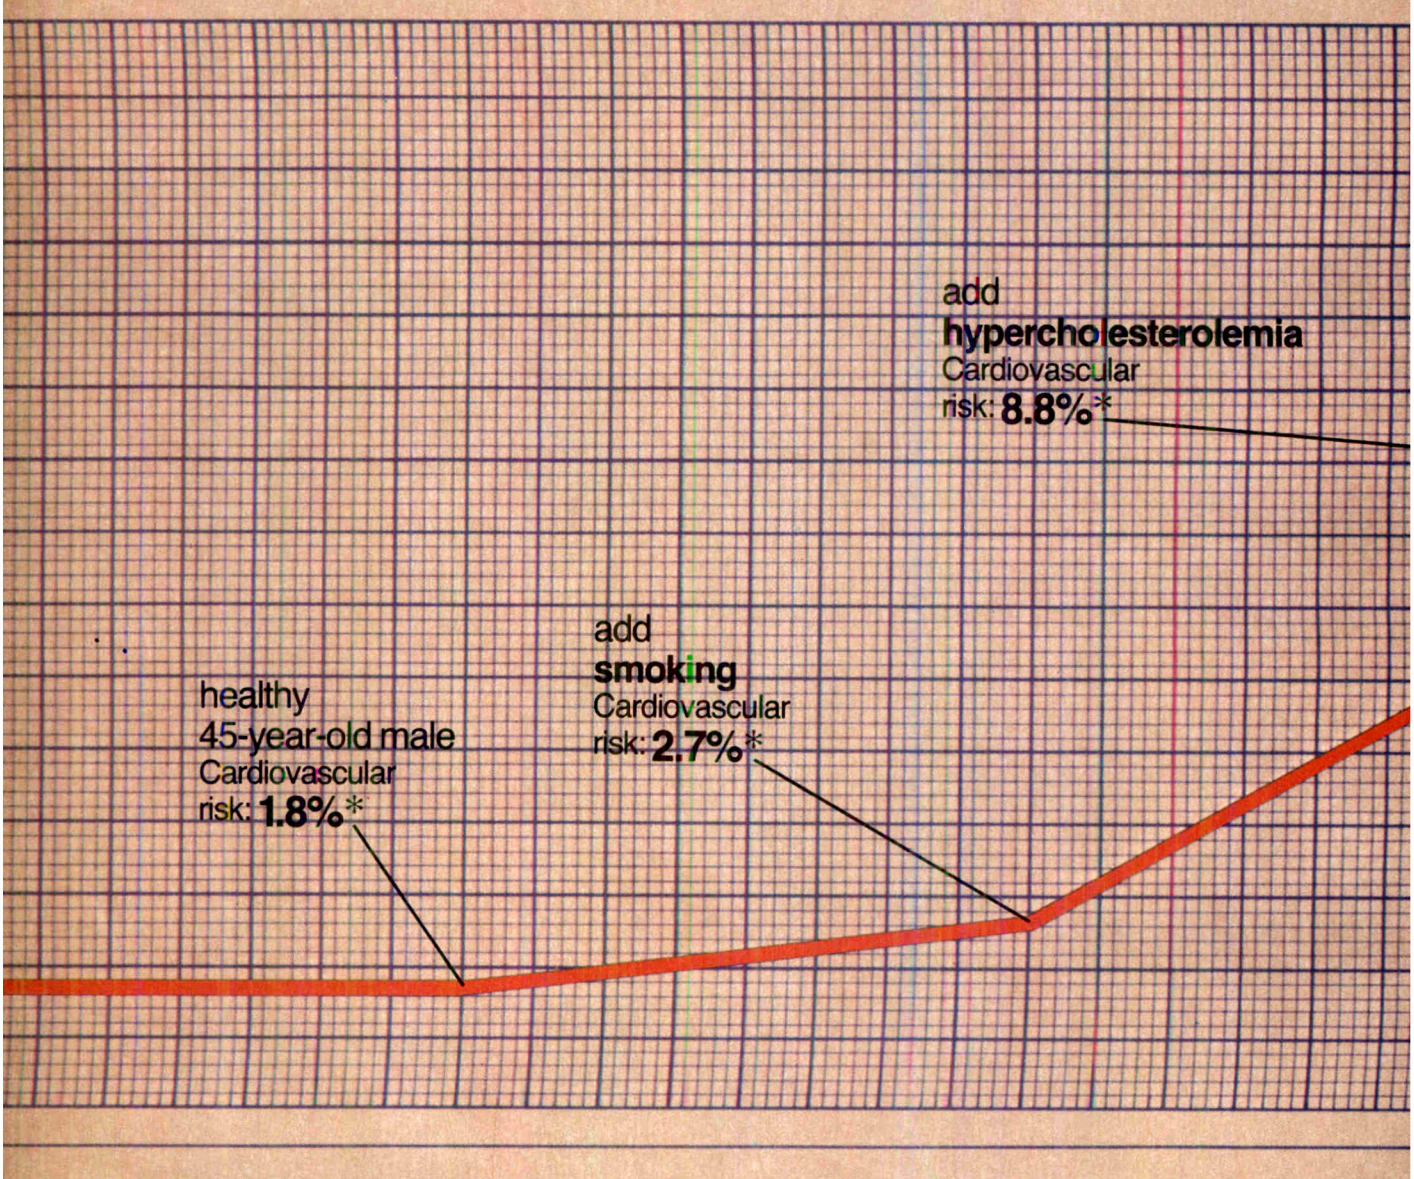
Meeting your diagnostic requirements...into the future.

MG/5310-017 SIQ 327

In hypertensive patients

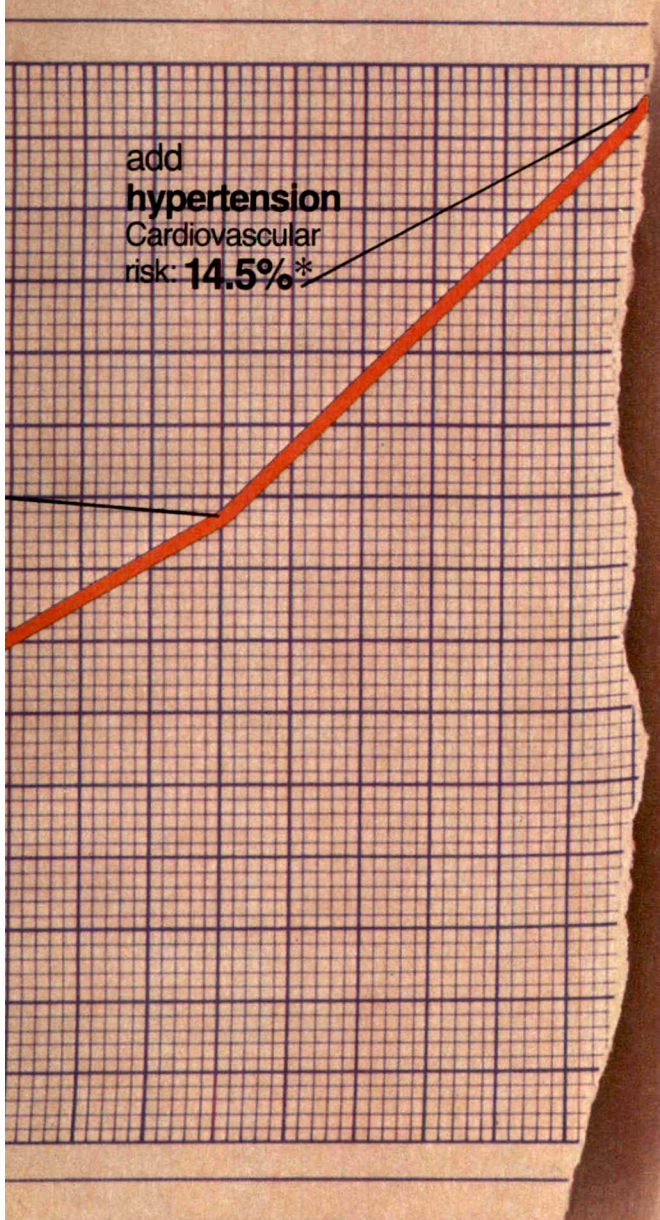


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



- When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

- Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

- Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1mg 2mg 5mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure...a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

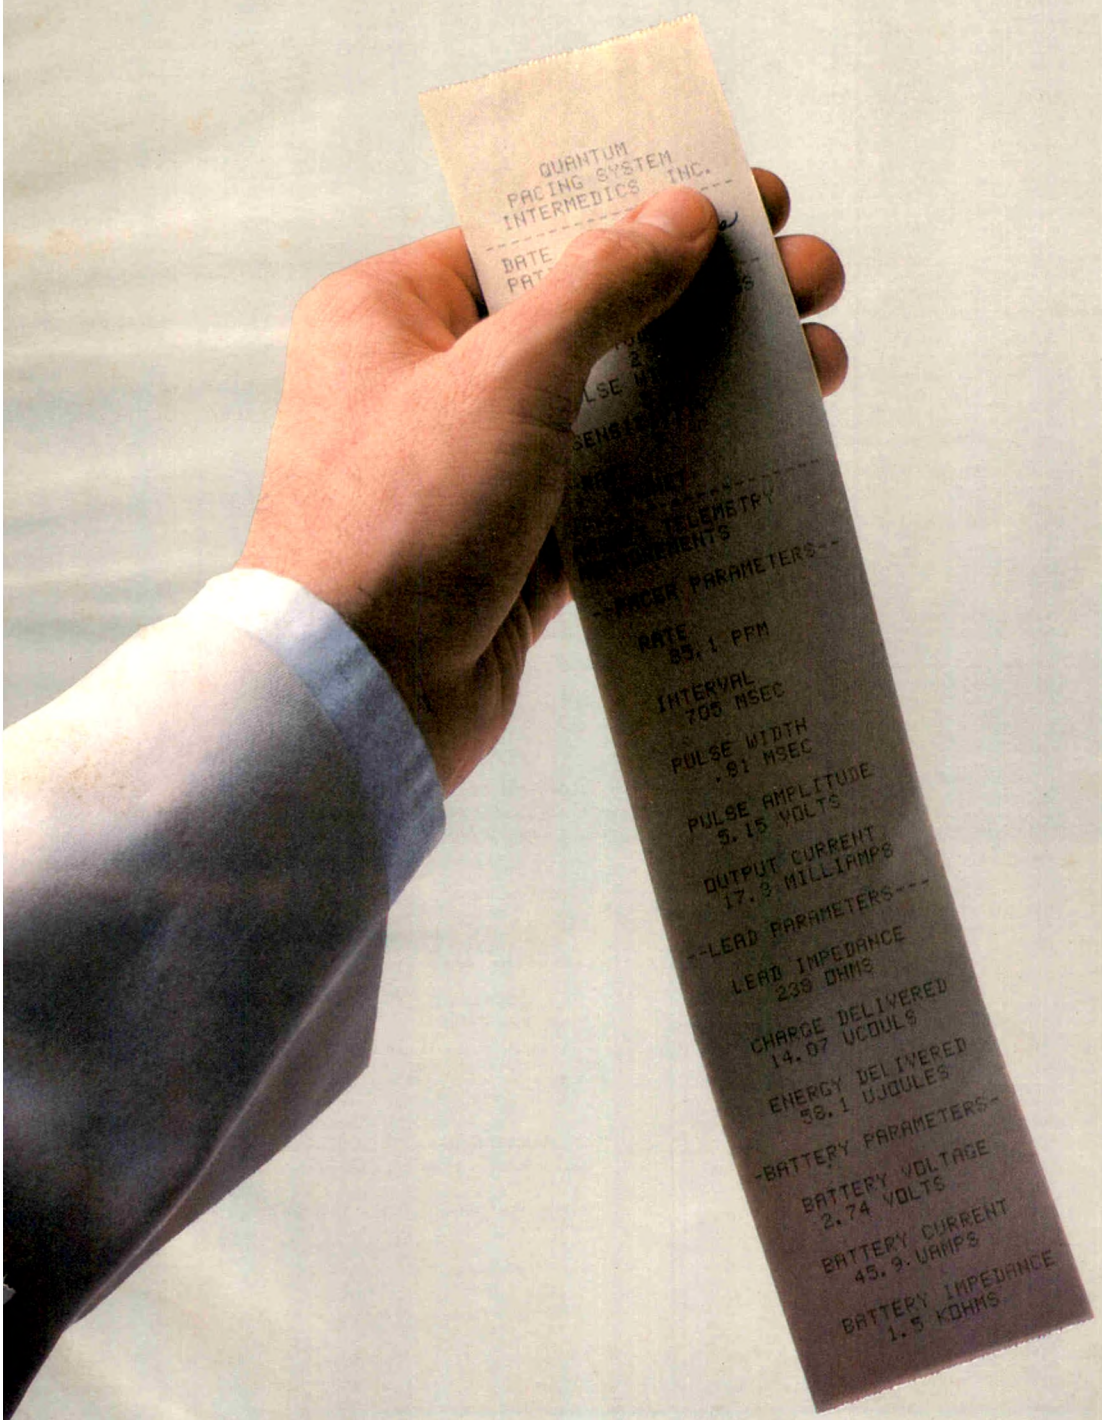
QUANTUM™

Intermedics Takes The Quantum Leap In Advanced Telemetry.



Better patient management with instant telemetry.

Quantum™ Gives You Actual
From Across The Room

More clinical data for better patient management.
Now physicians can quickly and easily get parametric data never before available from an implanted pacemaker. Whether your patient is in your office, at home, or across the country, Quantum gives you instant access to the condition of his pacing system via sophisticated telemetry transmission. The easy-to-learn, easy-to-use Quantum system requires no complicated electronic instrumentation. Just place the telemetry decoder over the patient's implanted pacemaker, press the measure key, and receive a digital display of pacing parameters. For remote monitoring the patient transmits the data to the decoder over the phone. It couldn't be simpler.

Printed records for accurate patient files.
The Quantum printer gives you an automatic printout of all measured data for permanent record keeping. Just place the decoder on the printer and press the button. Your files will be accurate and complete.

At the touch of a button you get:

- Pacemaker parameters: Rate, interval, pulse width, pulse amplitude, sensitivity setting and output current.
- Lead parameters: Impedance, charge delivered and energy delivered.
- Battery parameters: Voltage, current and impedance.

More information makes your clinical decisions easier.
Quantum provides you with more patient information than any other system available. It offers complete pacing data in the programmed mode or the magnet mode, at your option.
With this information, you can confirm the pacemaker's

Pacemaker Operating Data Or Across The World.

peration, and determine what adjustments to make for best results. atient management is easier and more comprehensive.

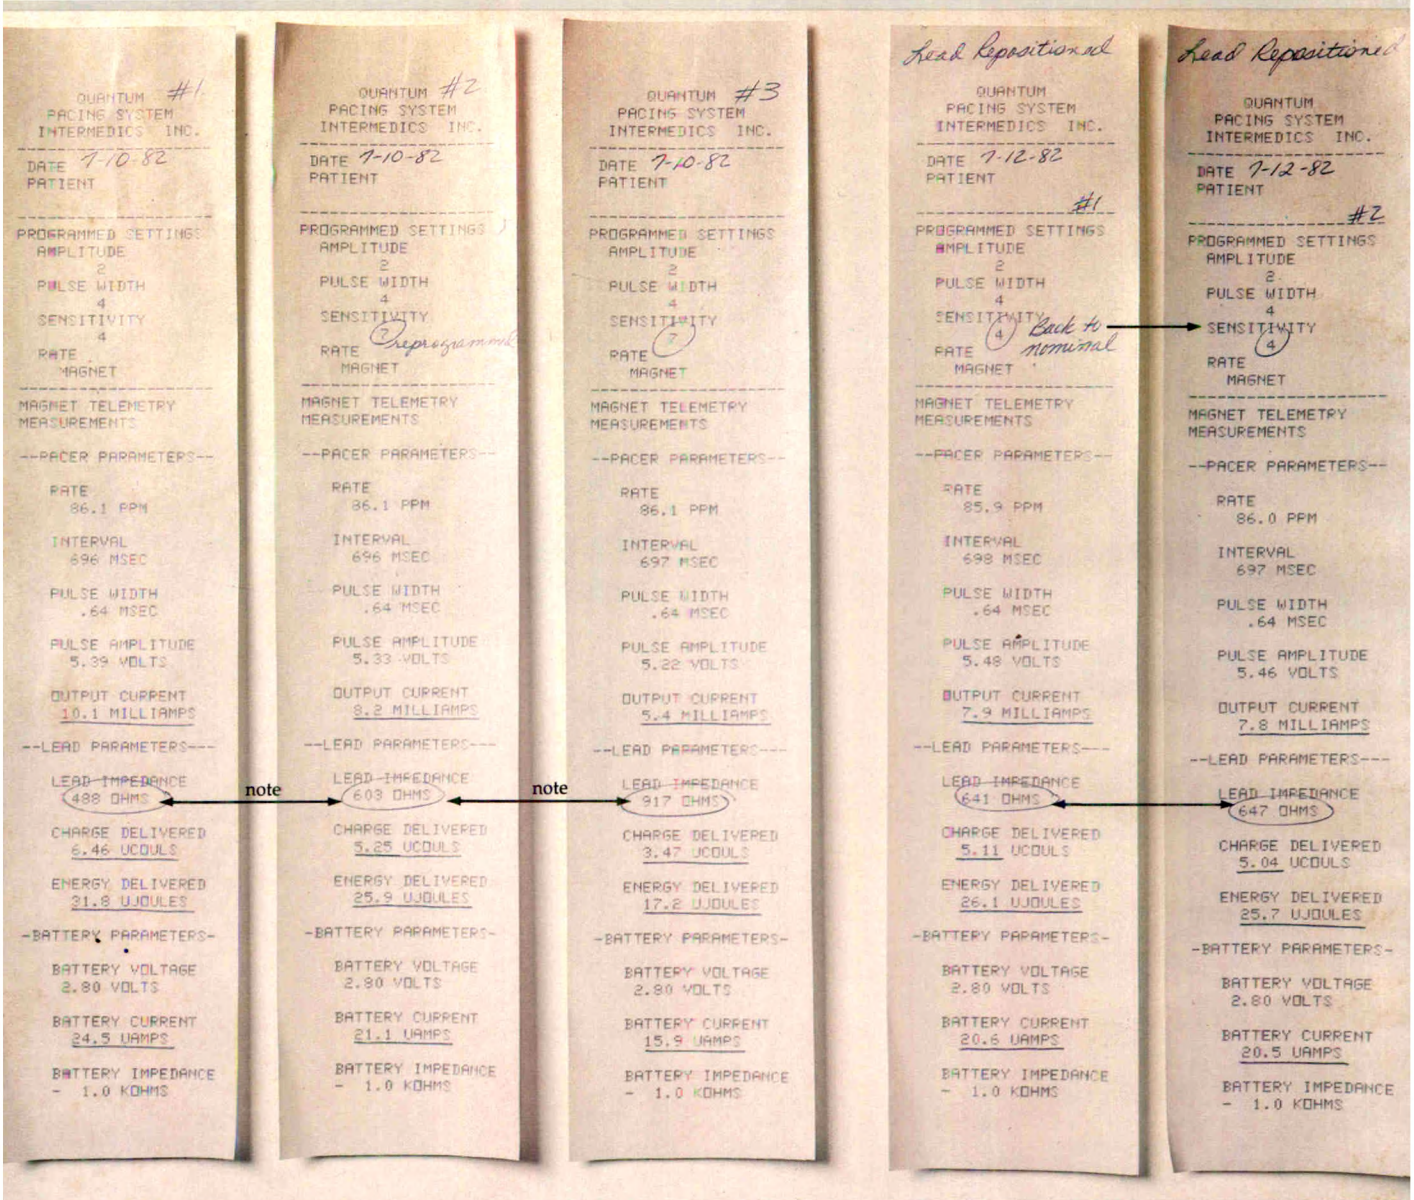
xpanded programming plus telemetry mean better patient anagement.

Quantum offers complete output tuning capabilities with programnable pulse amplitude and pulse width. This allows the physiian to determine strength/duration curves non-invasively and o program the pacemaker to assure capture while conserving nergy.

In addition to amplitude and pulse width, Quantum offers full selection of pacing rates, sensitivities, and modes. hese expanded programming options combined with Quantum's sophisticated telemetry, mean improved cute and chronic patient management.

Quantum is a complete pacing system, including Decoder, Printer, Transmitter, Intermedics rogrammer, and three pacemakers, representng the most sophisticated technology availble today. Take the Quantum Leap to better atient management.

Quantum™ Telemetry Uncovers Lead Instability



An Actual Case History*

Patient: MALE
Age: 81 YEARS
Diagnosis: HEART BLOCK, BRADYCARDIA WITH EPISODES OF VENTRICULAR TACHYCARDIA
Indication for Pacing: ARRHYTHMIA (BRADYCARDIA) CONTROL

The patient received a Quantum model 253-09 pulse generator with a transvenous unipolar lead. Intra-operative fluoroscopy and threshold testing indicated acceptable lead position.

Eighteen hours post implant, telemetry measurements displayed lead parameters that fluctuated widely, as shown in three successive telemetry printouts. The patient was uncomfortable and while there was no evidence of loss of capture on the EKG, pacing and sensing were irregular. Further investigation and discussion between the cardiologist and implanting surgeon led to a decision to reposition the lead. Repositioning surgery was successful.

Normal pacing and sensing were observed after repositioning. Successive telemetry measurements showed stable lead parameters, verifying that a more satisfactory position had been achieved. The patient was discharged following good post-operative recovery and subsequent telemetry follow-up demonstrated chronic lead stability.

Verapamil Therapy for Prinzmetal's Variant Angina: Comparison With Placebo and Nifedipine

MICHAEL D. WINNIFORD, MD, STACEY M. JOHNSON, MD, DAVID R. MAURITSON, MD, JAMES S. RELLAS, MD, GREGORY A. REDISH, MD, JAMES T. WILLERSON, MD, and L. DAVID HILLIS, MD

This study was performed (1) to assess the efficacy and safety of verapamil in patients with variant angina, and (2) to compare verapamil and nifedipine in patients with this clinical syndrome. In 27 patients, placebo and verapamil were administered in a long-term, randomized, and double-blind study of 9 months' duration. In comparison to placebo, verapamil reduced the frequency of angina, nitroglycerin usage, transient episodes of electrocardiographic S-T segment deviation (as assessed by 2-channel Holter monitoring), and hospitalizations required for clinical instability. Subsequently, 23 patients were treated with nifedipine in a nonblind fashion for 2 months, and this agent exerted a beneficial effect similar to that of verapamil. Finally, gated equilibrium blood pool scintigraphy, performed in 10 patients at rest and during exercise during treatment with placebo, verapamil, and nifedipine, demonstrated that neither calcium antagonist caused a deterioration of left ventricular performance. Thus, (1) long-term oral verapamil and nifedipine are each superior to placebo and are of similar efficacy in patients with variant angina, and (2) neither agent adversely influences left ventricular performance in patients with relatively normal left ventricular function.

Over the past 15 to 20 years, a group of pharmacologic agents known as calcium channel antagonists have been used outside the USA for the treatment of several forms of coronary heart disease.[1,2] These agents inhibit the movement of calcium from the extracellular to the intracellular space in cardiac and arterial smooth muscle and, as a result, may diminish both arterial tone and myocardial contractility. Of the available calcium blocking drugs, verapamil and nifedipine appear promising in the therapy of ischemic heart disease. Although preliminary experience shows that these drugs are especially effective in patients with variant angina,[3–9] these clinical trials have been uncontrolled or have administered the drugs for short periods of time; furthermore, no attempt has been made to compare verapamil and nifedipine in patients with this clinical syndrome.

Both verapamil and nifedipine possess direct negative inotropic effects in isolated cardiac muscle preparations[10,11]; however, neither agent exerts important negative inotropic effects in vivo, largely because of the direct systemic vasodilator actions exerted by both drugs,[11,12] which, by stimulating sympathetic reflexes and reducing ventricular afterload, offset the negative effects of these agents on myocardial contractility.[13–16] Although differences between the effects of verapamil and nifedipine on cardiac performance are thought to exist,[17] these beliefs are based largely on acute studies using large doses of both drugs administered parenterally; the *long-term* effects of *oral* administration of these drugs on ventricular function have not been compared in the same patients with angina pectoris.

From the Department of Internal Medicine (Cardiovascular Division), the University of Texas Health Science Center, Dallas, Texas. This work was supported in part by Ischemic SCOR Grant HL-17669 from the National Institutes of Health, Bethesda, Maryland, as well as the Harry S. Moss Heart Fund, Dallas, Texas.

Address for reprints: L. David Hillis, MD, Room L5.134, University of Texas Health Science Center, 5323 Harry Hines Boulevard, Dallas, Texas 75235.

The present study was designed to address three questions: (1) Is verapamil a safe and effective pharmacologic agent in patients with variant angina? (2) Are verapamil and nifedipine of similar efficacy in patients with this clinical syndrome? and (3) Does the long-term oral administration of verapamil or nifedipine exert a depressant effect on left ventricular performance in patients with variant angina?

Methods

Long-term, randomized, and double-blind comparison of placebo and verapamil in patients with variant angina: Twenty-seven patients (19 men, 8 women, average age 52 years) with recurrent episodes of angina at rest and concomitant transient S-T segment elevation were enrolled in a comparison of placebo and verapamil (450 ± 16 mg/day in 3 to 4 divided doses, mean ± standard error of the mean [SEM]; range 240 to 560 mg/day). Selective coronary arteriography in 26 patients revealed significant obstructive coronary artery disease (70% or greater luminal diameter narrowing) in 10, whereas the remaining 16 had coronary arterial spasm superimposed on angiographically normal coronary arteries. In addition to placebo or verapamil, 15 patients were maintained throughout the study on a stable dose of oral isosorbide dinitrate (104 ± 17 mg/day in 4 to 6 divided doses); in each patient, this dose was held constant throughout all treatment periods.

Individuals with any of the following were excluded from the study: (1) underlying diseases, including congestive heart failure, uncontrolled systemic arterial hypertension, hypotension, associated valvular or congenital cardiac disease, sick sinus syndrome, insulin-dependent diabetes mellitus, renal or hepatic disease, or any terminal illness; (2) certain electrocardiographic abnormalities (left bundle branch block, severe bradycardia, 2nd or 3rd degree atrioventricular block, atrial flutter or fibrillation, or preexcitation syndrome); or (3) the concomitant administration of disopyramide or beta-adrenergic blocking agents.

After a diagnosis of variant angina was established and informed consent was obtained, each patient received open-label verapamil for one month, during which time the dose of the drug was advanced upwards, so as to achieve an optimal effect without adverse effects. Subsequently, each patient was randomly and blindly assigned to 1 of 2 groups for the next 8 months: four 2 month blocks of placebo alternating with verapamil. If frequent rest angina was accompanied by electrocardiographic evidence of ischemia and required hospitalization, the patient was blindly advanced to the next therapy. During the 8 months of blinded therapy, several variables were assessed: (1) number of episodes of chest pain per week, (2) number of nitroglycerin tablets used per week, and (3) number of adverse effects, all recorded daily by the patient in a diary; (4) number of hospitalizations required for severe chest pain; and (5) number of episodes of transient S-T segment deviation (elevation or depression of 0.1 mV or greater) on weekly 24 hour 2-channel ambulatory electrocardiographic monitoring; analysis of the Holter monitor recordings was performed as described previously.[18]

All variables were analyzed without knowledge of the order in which placebo and verapamil were administered. For each variable, the 4 months of placebo therapy were averaged and compared with the average of the 4 months of verapamil therapy with a paired t test and Wilcoxon matched-pairs signed ranks test. All values were reported as mean ± SEM. For all analyses, a p value less than 0.05 was considered significant.

Comparison of verapamil and nifedipine: clinical efficacy: The first 23 patients to complete the long-term comparison of placebo and verapamil (just described) were enrolled in an additional 2 months of nifedipine therapy. During these 2 months, nifedipine was administered as an open-label medication (that is, neither blinded nor randomized) in the maximally tolerated dose (71 ± 5 mg/day in 3 to 4 equal doses; range, 40 to 160 mg/day). Thus, in all 23 patients, both verapamil and nifedipine were administered in dosages that afforded maximal relief of angina without limiting adverse effects. In addition to placebo, verapamil, or nifedipine, 14 patients were treated with a stable dose of oral isosorbide dinitrate which was unchanged throughout the 3 treatment periods (116 ± 18 mg/day in 4 to 6 divided doses; range, 40 to 200 mg/day). During this additional 2 month period of nifedipine therapy, the variables assessed during the long-term comparison of placebo and verapamil were similarly measured.

For the purpose of data analysis, each variable was quantitated during the latter 4 months of blinded therapy (2 months of placebo, 2 months of verapamil) as well as the 2 months of nifedipine therapy. A repeated measures analysis of variance was performed for each variable to determine if some groups were different from others, after which the Newman-Keuls multiple comparison procedure was performed. The Friedman chi-square nonparametric test[19] was also used to evaluate each variable, after which nonparametric multiple comparisons were performed. When the effects of nonnormality were sufficient to cause disagreement between parametric and nonparametric procedures, results of the nonparametric analysis were reported. All values were expressed as mean ± standard error; a p value of 0.05 or less was considered significant.

Comparison of verapamil and nifedipine: effects on left ventricular function: During the final week of the last 3 of the five 2-month treatment periods (that is, at the end of months 6, 8, and 10), 10 of the patients underwent equilibrium gated blood pool scintigraphy at rest and during supine bicycle exercise. All exercise studies were performed 1 to 2 hours after a regularly scheduled dose of medication (placebo, verapamil, or nifedipine). Multigated equilibrium blood pool imaging was performed after in vivo labeling of red blood cells with 30 mCi of technetium-99m sodium pertechnetate, according to the technique previously described.[20,21] Data collection was performed with a portable gamma scintillation camera (Ohio Nuclear VIP-450). Resting and exercise gated blood pool scintigrams were obtained in a modified left anterior oblique projection; the angle of obliquity was adjusted to allow the clearest separation between the ventricles while minimizing the interventricular septal thickness. Resting images were acquired for (1) a predetermined number of cardiac cycles, so that the total acquisition time was 5 to 8 minutes; (2) 32 frames/cardiac cycle; and (3) 100% of the cardiac cycle. The result was a minimum of 150,000 counts/frame of the study.

Each subject's feet were elevated and attached to the bicycle pedals before beginning the exercise study. After a 3 minute equilibration period, an additional resting scintigram was obtained to assess the effect of leg elevation on the variables measured. These and subsequent exercise images were acquired for (1) a predetermined number of cardiac cycles, so that the total acquisition time during exercise was 3 minutes; (2) 32 frames/cardiac cycle; and (3) 100% of the cardiac cycle. This provided a minimum of 100,000 counts per frame during

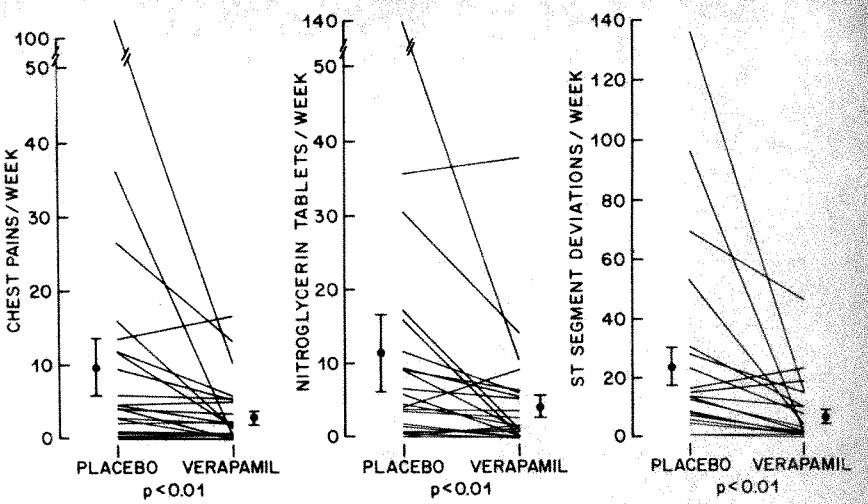

FIGURE 1. The number of anginal episodes per week (**left panel**), the number of nitroglycerin tablets used per week (**middle panel**) and the number of transient S-T segment deviations per week by 2 channel ambulatory electrocardiographic monitoring (**right panel**) during 4 months of placebo therapy and 4 months of treatment with verapamil in 27 patients with Prinzmetal's variant angina. **Each line** represents the data from one patient, and the means ± SEM are displayed on either side of each set of lines. In comparison with placebo, verapamil reduced the frequency of all 3 variables.

exercise. Imaging was performed at each work load, beginning at 150 kilopond-meters per minute (kpm/min) and continuing until the termination of the test. At the beginning of the 1st and each subsequent work load, the subject exercised for 1 minute before beginning the 3 minute imaging period, which allowed the heart rate to reach a new steady level and uninterrupted gating to occur. During acquisition of scintigraphic data, heart rate did not vary by more than 15% of the value recorded at the start of the acquisition period. The Frank lead system or a truncal 12 lead system was used for electrocardiographic monitoring, and the blood pressure was recorded by auscultation at rest and during each work load. Left ventricular volumes and ejection fraction were determined with a nongeometric technique developed and validated in our laboratory[22,23] and in others.[24]

During each of the three exercise studies, the maximal achieved work load was determined. Both at rest and during the maximal work load common to all 3 exercise studies, the following variables were analyzed: heart rate, systolic blood pressure, left ventricular end-diastolic volume index, left ventricular end-systolic volume index, and left ventricular ejection fraction. For each variable (at rest and during exercise), a repeated measures analysis of variance was performed to determine if 2 or more groups were different from one another, after which the groups were compared using the Newman-Keuls mutiple comparison procedure.[18,19] When changes from rest to exercise were assessed for one of the 3 agents, the paired t test was employed. A probability (p) value of less than 0.05 was considered significant.

Results

Long-term, randomized, double-blinded comparison of placebo and verapamil in patients with variant angina: During verapamil administration, the frequency of chest pain, nitroglycerin utilization, and transient S-T segment deviations by ambulatory electrocardiographic monitoring decreased in comparison with the effects of the placebo (Fig. 1). During verapamil therapy, 1 patient died, but none required hospitalization for clinical instability. In contrast, during placebo therapy, 7 patients had at least one episode of clinical instability requiring hospitalization or a blind advancement in medication sequence ($p < 0.025$). In each case, an advancement to verapamil therapy resulted in relief of symptoms.

Comparison of verapamil and nifedipine: clinical efficacy: During therapy with both verapamil and nifedipine, the frequency of angina was reduced in comparison with that during placebo (Fig. 2). Similarly, nitroglycerin consumption and the number of episodes of transient S-T segment deviation on calibrated 2 channel ambulatory electrocardiographic monitoring were less during therapy with verapamil and nifedipine than during placebo (Fig. 2).

During placebo therapy, 7 of the 23 patients required hospitalization because of severe angina; 2 patients required hospitalization for chest pain during nifedipine therapy ($p = 0.06$ in comparison with placebo), and no patient was hospitalized during treatment with verapamil ($p < 0.01$ in comparison with placebo). No patient had myocardial infarction or died.

Comparison of placebo, verapamil, and nifedipine: adverse effects: adverse reactions were observed during long-term placebo, verapamil, and nifedipine therapy that were not noted during the initial dose titration phase for each agent. During long-term therapy with placebo, 1 patient reported constipation and 1 developed abdominal distention. During long-term verapamil administration, 1 patient had palpitations (in conjunction with an accelerated atrioventricular nodal rhythm on ambulatory electrocardiographic monitoring), 2 had asymptomatic prolongation of the P-R interval (>0.20 seconds), and 5 had constipation. None of these forced a discontinuation or reduction in the dosage of verapamil in any patient. During long-term nifedipine therapy, 10 patients had adverse effects. One patient had headache and orthostatic hypotension which forced a premature termination of nifedipine. In 2 patients headache and nonorthostatic dizziness developed which mandated a discontinuation of nifedipine after 1 month. Seven others had dose-limiting adverse effects, including orthostatic hypotension in 2, pedal edema in 1, nausea, anorexia, and nonorthostatic dizziness in 3, and headache in 1.

Comparison of verapamil and nifedipine: effects on left ventricular function (Table I): Resting heart rate was lower during verapamil therapy than during treatment with nifedipine, but resting systolic arterial pressure was similar during treatment with placebo and both active drugs. The maximal work load achieved by each patient was similar during the 3 treatment periods; at this maximal work load, heart rate and systolic arterial pressure increased during treatment with all 3 agents, but remained lower during verapamil therapy compared with the placebo. Resting left ventricular end-diastolic volume index, end-systolic volume index, and ejection fraction did not differ significantly among the 3 treatment periods; at the maximal common work load, ejection fraction increased to a similar degree during therapy with all agents (Table I, Fig. 3).

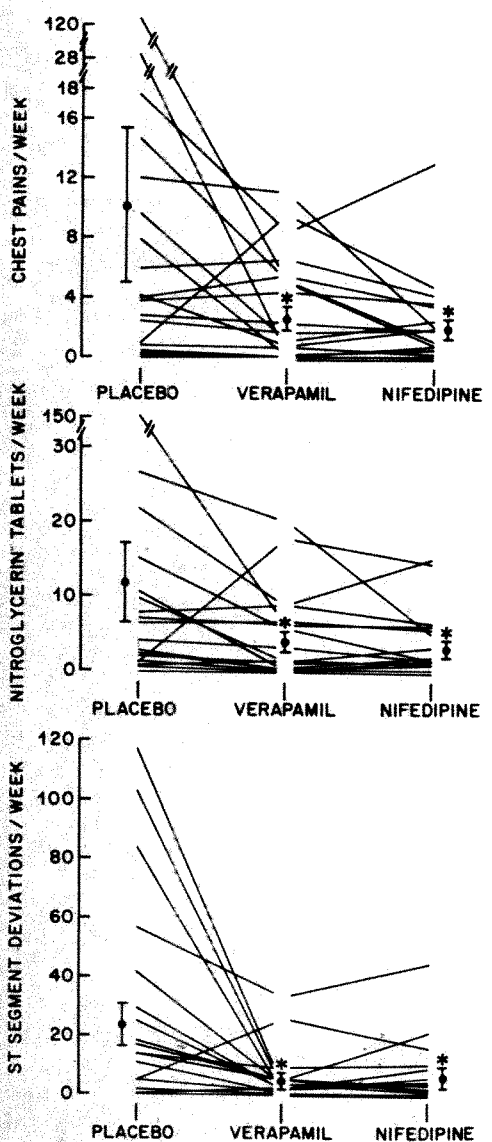

FIGURE 2. Number of anginal episodes per week (**top panel**), nitroglycerin tablets consumed per week (**middle panel**), and transient S-T segment deviations by 2 channel ambulatory electrocardiographic monitoring (**lower panel**) during placebo (**left**), verapamil (**middle**), and nifedipine (**right**) in 23 patients with variant angina pectoris. **Each line** represents the data from one patient, and the means ± SEM are shown for each treatment period. In comparison with placebo, both verapamil and nifedipine reduced the frequency of all 3 variables, and there was no difference between the two drugs. **Asterisks** indicate $p < 0.05$ in comparison with placebo.

Discussion

Over the past two decades, a group of pharmacologic agents known as the calcium antagonists has been used outside the United States for the treatment of several forms of ischemic heart disease, including Prinzmetal's variant angina. Preliminary observations have shown that these agents are effective in this syndrome,[3–9,25,26] but few studies have assessed the utility of these drugs in a randomized, controlled, and blind fashion or have compared the different calcium antagonists with one another. The studies described herein demonstrate that verapamil is safe and effective in the long-term management of patients with variant angina and that it is similar in efficacy to nifedipine in the therapy of these patients.

Verapamil versus placebo in patients with Prinzmetal's variant angina: Since its introduction in Europe in 1962, verapamil has been used for the treatment of patients with supraventricular tachyarrhythmias,[27,28] essential systemic hypertension, hypertrophic cardiomyopathy,[29,30] and several forms of coronary heart disease. Previous uncontrolled studies have suggested that verapamil is beneficial in patients with Prinzmetal's variant angina pectoris,[3–6] the clinical syndrome of chest pain and concomitant S-T segment elevation due to coronary arterial spasm.[31] The present randomized, blind, and long-term evaluation demonstrates verapamil's efficacy in patients with this disease. In comparison with placebo, verapamil reduced the

All figures are mean ± standard error of the mean. HR = heart rate; kpm/min = kilopondmeters/minute; LVEF = left ventricular ejection fraction; LVEDVI = left ventricular end-diastolic volume index; LVESVI = left ventricular end-systolic volume index.

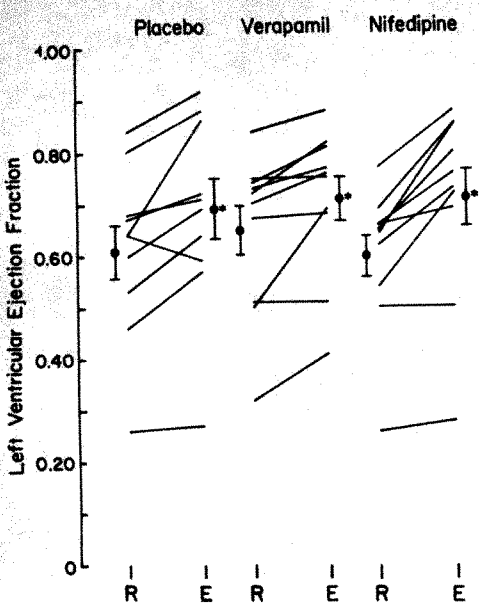

FIGURE 3. Left ventricular ejection fraction at rest (R) and at the maximal work load common to all 3 exercise studies (E) for the 3 therapy periods. **Each line** represents the data from one patient, and the mean values ± SEM are depicted on either side of the lines. At rest and during exercise, values during the 3 treatment periods were similar. **Asterisks** indicate $p < 0.05$ when compared with the same pharmacologic agent at rest.

frequency of both anginal episodes and nitroglycerin utilization, decreased the number of episodes of clinical instability requiring hospitalization, and reduced the frequency of transient S-T segment deviations, as detected by 2 channel ambulatory electrocardiographic monitoring. Furthermore, verapamil was well tolerated; adverse effects were relatively minor and did not limit its administration.

Verapamil versus nifedipine in patients with Prinzmetal's variant angina: clinical efficacy: Because of its dilator actions on systemic and coronary arteries, nifedipine has been used to treat systemic hypertension,[32] angina of effort,[33,34] angina at rest,[35] and variant angina.[7–9] It has also been used (in a limited manner) as a myocardial "protectant" during cardiopulmonary bypass.[36]

The present study demonstrates that verapamil and nifedipine are of similar efficacy in patients with variant angina pectoris. Both agents reduced the frequency of angina and nitroglycerin utilization, and both drugs diminished the frequency of transient ischemic S-T segment alterations by calibrated 2 channel ambulatory electrocardiographic monitoring. However, adverse effects occurred more frequently with nifedipine than with verapamil. In 10 of the 23 patients who received both drugs, adverse reactions limited the amount of nifedipine that could be administered; in contrast, side effects during verapamil administration were relatively minor and did not alter the dosage.

This comparison of verapamil and nifedipine in patients with variant angina has certain limitations. Although placebo and verapamil were administered as part of a randomized and double-blind evaluation, nifedipine was administered as an "open-label" medication; hence, investigator and patient bias may have influenced our results in favor of nifedipine. Furthermore, whereas verapamil and placebo therapies were compared in random order, verapamil and nifedipine were not so compared; the cyclic nature of ischemic episodes in variant angina may have led to a spontaneous decrease in the number of ischemic episodes recorded during the latter phases of this study, and thus would have favored our finding a favorable result with nifedipine. Further studies will require the blind administration of all 3 pharmacologic agents with placebo periods before and after the administration of each active drug. With these limitations in mind, this study shows that verapamil and nifedipine are highly beneficial and are of similar efficacy in the therapy of patients with variant angina. Thus, the availability of both calcium antagonists makes it possible for each patient with variant angina to receive the drug optimally suited for his specific needs. If he cannot tolerate one of them, the other can be administered and a similar salutary effect anticipated.

Verapamil versus nifedipine in patients with Prinzmetal's variant angina: effects on left ventricular function: Because verapamil diminishes the rate of spontaneous impulse initiation by the sinoatrial node[37] as well as the rate of conduction through atrioventricular tissue,[38] it is extremely effective in the therapy of supraventricular tachyarrhythmias[39,40]; in contrast, nifedipine exerts no discernible effects on the cardiac conduction system. Although both drugs possess direct negative inotropic effects in vitro,[10,11] the peripheral vasodilator actions of verapamil and nifedipine offset these negative inotropic effects in man.[14,15] Neutralization of these cardiodepressant effects by peripheral vasodilation is thought to be more complete with nifedipine[17]; hence, nifedipine is frequently regarded as exerting less overall negative effects on cardiac performance. However, this presumption has largely been based on the acute effects of rather large doses given parenterally. Previous studies have not compared the effects of the *long-term oral* administration of verapamil and nifedipine on left ventricular performance in the same patients.

In the present study we compared the effects of long-term therapy with placebo, verapamil, and nifedipine on left ventricular performance in 10 patients with variant angina. Left ventricular volumes and ejection fraction were similar during the 3 treatment periods both at rest and during exercise, even in the 2 patients with depressed left ventricular performance. Therefore, although previous studies showed that high concentrations of intravenously administered verapamil exert a substantial negative inotropic effect in animal studies,[41] this study demonstrates that long-term, orally administered verapamil does not adversely affect left ventricular performance either at rest or during exercise.

Of the 10 patients comprising this study, 8 had resting left ventricular ejection fractions during placebo therapy above 0.50, whereas in the remaining 2 the resting

ejection fractions on placebo were 0.46 and 0.26. Neither patient manifested symptoms or signs of left ventricular failure. Both tolerated verapamil without difficulty, and, in fact, their resting left ventricular ejection fractions increased to 0.51 and 0.32, respectively. Similarly, nifedipine was administered to both without problems, and the resting ejection fractions during this therapy were 0.50 and 0.26, respectively. Thus, neither verapamil nor nifedipine caused a worsening of left ventricular performance even in the 2 patients with a substantial depression of ejection fraction. Although these results are encouraging, they should be extrapolated cautiously to a larger group of patients with depressed left ventricular performance, especially those who manifest evidence of left ventricular failure.

Verapamil Therapy for Unstable Angina Pectoris: Review of Double-Blind Placebo-Controlled Randomized Clinical Trials

JAWAHAR MEHTA, MD and C. RICHARD CONTI, MD

The effectiveness of verapamil in the management of patients with unstable angina pectoris associated with obstructive coronary artery disease was evaluated in 2 double-blind placebo-controlled randomized clinical trials. In the 1st study, verapamil was compared with placebo using alternating 48 hour treatment periods in a multiple cross-over protocol. Verapamil was superior to placebo in abolishing symptomatic and asymptomatic ischemic episodes; there were 127 ischemic events during treatment with placebo but only 27 episodes during therapy with verapamil ($p < 0.006$). In the 2nd study, verapamil and placebo were compared using a double-blind randomized parallel design in which the choice of drug was altered and the doses administered were increased according to the individual responses. Verapamil reduced anginal attacks in 12 of 13 patients, but placebo was effective in only 1 of 6 ($p < 0.025$); verapamil reduced daily anginal attacks from 3.2 to 0.6/day ($p < 0.01$). Thus, verapamil is highly effective in the short-term management of patients with unstable angina secondary to coronary artery disease.

The management of patients with unstable angina pectoris continues to be a difficult clinical problem.[1] Although the choice between initial surgical and medical therapy appears to favor a nonsurgical approach, continued controversy surrounds the choice of medical treatment regimens.

A rational approach to the management of patients with unstable angina should be based on an understanding of the pathogenesis of the syndrome. Because many patients with unstable angina have little or no change in blood pressure and heart rate at the onset of their symptoms,[2] coronary artery spasm and in vivo platelet aggregation are important mechanisms by which the magnitude of fixed obstruction secondary to coronary atherosclerosis may be transiently exacerbated.[3] Decreased oxygen supply rather than increased demand may be the primary pathogenetic mechanism of myocardial ischemia in patients with unstable angina[4]; hence, treatment of such patients with beta-adrenergic blocking agents has been questioned, because these agents may have deleterious effects in patients with coronary artery spasm.[5] Nitrates exert beneficial effects on both myocardial oxygen demand and supply[6–8] and hence are widely used in the treatment of unstable angina[9]; however, many patients fail to respond to nitrates alone, experience prohibitive adverse reactions, or find them inconvenient for long-term therapy.

The class of drugs known as the calcium antagonists possess a number of pharmacologic properties that may be beneficial in patients with angina pectoris at rest or on exertion. These drugs are potent systemic vasodilator agents and act either directly by blocking the entry of calcium into vascular smooth muscle[10] or indirectly by a sympatholytic effect[11,12]; this systemic vasodilation should reduce myocardial oxygen requirements at any given level of work.[13] In addition, these agents may specifically act on dynamic factors in the coronary circulation, which predispose to vasospasm; this action may be accomplished by direct antagonism of spontaneous smooth muscle contraction[14] or indirectly by inhibition of platelet aggregation[15–17] and of thromboxane A_2 synthesis (unpublished observations). Accordingly, several recent trials of slow channel calcium antagonists have produced encouraging results in patients with exertional and variant angina[18–23]; recent studies indicate that these agents may also be beneficial in patients with unstable angina.[24–27]

The purpose of this report is to review the clinical effectiveness of one of these calcium antagonists, verapamil, in the short-term management of patients with unstable angina associated with obstructive coronary artery disease.

Double-Blind Multiple Cross-Over Trial in Unstable Angina

In 1979 Parodi et al.[24] reported the 1st placebo-controlled trial of verapamil in patients with unstable angina.

Patients: These investigators evaluated 12 patients (aged 34 to 70 years, mean 54), 7 of whom had both exertional and rest angina, whereas 5 had only rest angina with normal exercise tolerance. The electrocardiogram during the ischemic event revealed S-T segment ele-

From the Division of Cardiology, Department of Medicine, University of Florida, College of Medicine, and the Veteran's Administration Medical Center, Gainesville, Florida.

vation in 6, depression in 4, and alternate elevation and depression in the same lead in the remaining 2 patients. A massive reduction of myocardial perfusion during a spontaneous angina attack was documented in all 8 patients in whom thallium-201 was injected at the beginning of an ischemic episode. Coronary angiography was performed in 9 patients and showed significant obstructive coronary artery disease (greater than 50% coronary luminal narrowing) in 8.

Protocol design: The study protocol consisted of a 2 day run-in period while patients received diazepam, followed by four 2 day treatment periods consisting of either placebo or verapamil (480 mg daily) in alternating randomized fashion. The efficacy of therapy was determined by quantitating symptomatic and asymptomatic episodes of S-T segment depression or elevation during continuous electrocardiographic monitoring.

Results: For the group of patients as a whole, the number of S-T segment shifts in the placebo run-in period and the 2 placebo periods was the same (128 versus 123 and 130 events, respectively). In contrast, during each period of verapamil treatment, a highly significant reduction in the number of episodes to 31 and 23 events was observed ($p < 0.006$). This reduction was similar in the number of episodes of S-T segment elevation or depression and of symptomatic and asymptomatic episodes (Fig. 1). In 2 patients, ischemic episodes were totally abolished during both verapamil treatment periods; in another 4 patients, verapamil therapy eliminated ischemic episodes entirely in 1 of the 2 treatment periods.

Side effects: The investigators reported muscle cramps and weakness, constipation, and transient mental confusion in one patient each during verapamil therapy. There were no significant effects on heart rate or blood pressure. The electrocardiographic P-R interval increased in 7 of 12 patients given verapamil, but first degree atrioventricular block (P-R interval greater than 0.20 second) developed in only 3 patients.

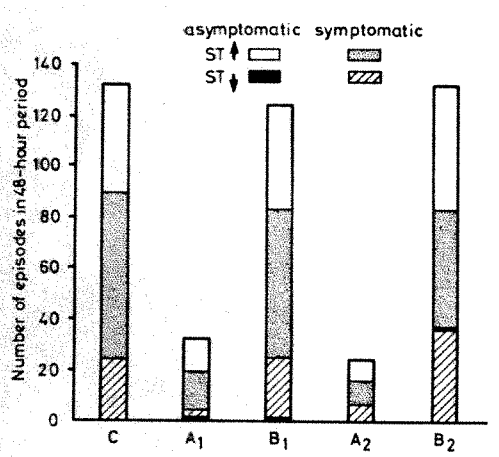

FIGURE 1. The total number of episodes in 12 patients in each 48 hour period of the trial. C indicates run-in period; A_1, A_2 = verapamil periods; B_1, B_2 = placebo periods. Control and placebo periods show similar number and type of ischemic episodes, whereas during treatment with verapamil there is a conspicuous reduction in frequency of all types of episodes. (Reproduced, with permission, from Parodi et al.[24])

Double-Blind Parallel Randomized Trial in Unstable Angina

Mehta et al.[25] in 1981 reported another placebo-controlled trial of verapamil in patients with unstable angina.

Patient population: These investigators evaluated 15 patients (out of 65 patients screened), who were experiencing angina at rest with at least 2 episodes of chest pain per 24 hours associated with S-T segment changes; patients with congestive heart failure, hypotension, and conduction system disease were excluded. Fourteen men and 1 woman (aged 42 to 80 years, mean 61) entered the study. Five patients had received prior therapy with beta-blocking drugs and all had received nitrates. Duration of angina before this study was 2 weeks to 11 years. In the preceding month, all patients had episodes of rest angina (range 1 to 30 per week), and 13 also had exertional angina (range 1 to 50 attacks per week). Twelve of the 15 patients had coronary angiography, and all had significant (greater than 50% narrowing) 2- or 3-vessel disease; 1 patient also had 60% luminal narrowing of the left main coronary artery.

Protocol design: All patients entered a single-blind placebo run-in period that lasted 24 hours, after which patients who continued to meet the criteria for the study were randomized to receive either placebo or verapamil (320 mg/day) in a double-blind fashion for the 2nd 24 hour period. At the end of the 2nd day, patients who were considered "responders" (defined as those having a 50% or greater reduction in the frequency of symptomatic rest angina) continued to take the same medication; patients who did not respond were crossed to receive verapamil: a nonresponder to placebo received verapamil 320 mg daily, whereas a nonresponder to verapamil (320 mg daily) was advanced to a dose of 480 mg daily. At the end of the 3rd day, a similar assessment of response was made; responders continued to take their "effective" drug, whereas nonresponders were crossed to low-dose verapamil (320 mg daily) or had their dose of verapamil increased (480 mg daily), as just discussed. The study was unblinded at the end of the 4th 24 hour period. Patients stayed on bedrest for the entire duration of the study. Sublingual nitroglycerin was permitted for relief of symptomatic ischemic episodes.

Results: During the 1st 24 hour single-blind placebo period, the frequency of angina episodes ranged from 2 to 8 (mean 3.2) and the number of nitroglycerin tablets consumed ranged from 0 to 9 (mean 3.1). With chest pain, 11 patients had S-T segment depression, 1 elevation, and the remaining 3 alternate depression and elevation in the same leads.

In the 2nd 24 hour period, 6 patients received placebo and the other 9 verapamil (Fig. 2). Only 1 of the 6 patients treated with placebo improved, whereas 7 of the 9 patients randomized to verapamil (320 mg daily) responded to therapy ($p < 0.025$ by Fisher's exact test); 1 patient failed to improve, and 1 patient developed evidence of myocardial necrosis which began before verapamil administration, and so was excluded from further

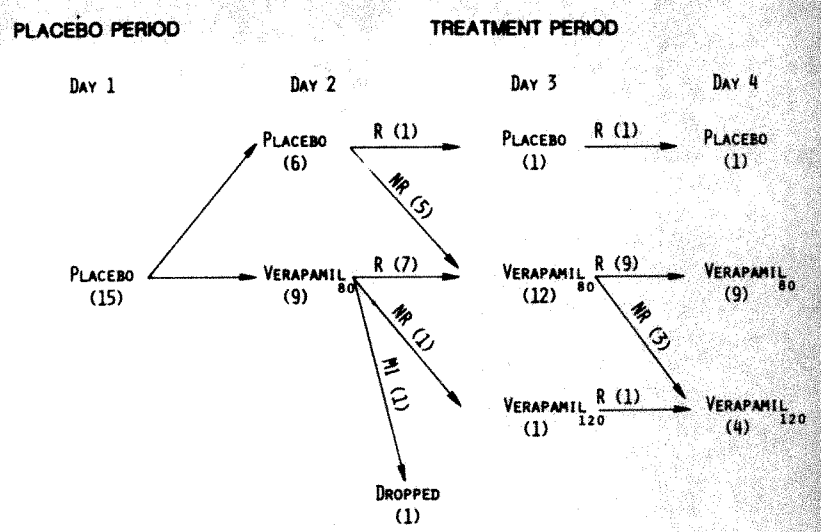

FIGURE 2. A summary of the protocol, treatment schedule, and response to therapy in 15 patients with rest angina. Verapamil 80 and 120 = 80 mg or 120 mg every 6 hours; R = responder; NR = nonresponder. At the end of day 4, there were 13 patients on verapamil and 1 on placebo. (Reproduced, with permission, from Mehta et al.[25])

study. The 5 patients who failed to respond to placebo were then treated with verapamil (320 mg daily), whereas the 1 patient who failed to respond to verapamil was advanced to large doses of verapamil (480 mg/day).

In the 3rd 24 hour period, the 1 placebo-responder continued to respond. Of the 13 patients on verapamil, 10 were responders and 3 nonresponders, and these were advanced to large doses of verapamil (480 mg/day) (Fig. 2).

In the 4th 24 hour period, 1 patient receiving placebo continued to respond (Fig. 2). Of the 13 patients receiving verapamil (320 mg/day in 9 patients and 480 mg/day in 4), all except 1 patient were responders to the drug; the latter patient received only 320 mg of verapamil daily. At the end of this short-term study, frequency of chest pain had decreased from 3.2 to 0.6 episodes per day, and nitroglycerin consumption had declined from 3.1 to 0.3 tablets per day ($p < 0.01$) compared with the 1st 24 hour placebo run-in period.

Side effects: Verapamil therapy was well tolerated with few side effects. There were no hematologic adverse effects or alterations in renal or hepatic function. Electrocardiographic P-R interval prolongation was noted in 2 patients; one of these had a decrease in the P-R interval when the dose of verapamil was decreased to 240 mg/day but still had sustained relief of anginal symptoms.

Discussion

Recent investigators have indicated that patients with variant and unstable angina at rest commonly exhibit dynamic alterations in their coronary circulation, which when superimposed on partially obstructive atherosclerotic lesions can result in a primary reduction in myocardial blood flow. Such dynamic factors include coronary artery vasospasm, in vivo platelet aggregation, and enhanced platelet prostaglandin generation.[28–30] Calcium channel blocking agents, such as verapamil, can abolish vasospasm, inhibit in vivo platelet aggregation, and block the synthesis of thromboxane A_2, and thereby antagonize specifically those dynamic factors that are critical in the pathogenesis of the unstable angina syndrome.

Necessity for placebo-controlled trials in unstable angina: Although a number of calcium-blocking agents have been effective in patients with angina at rest, these trials were largely uncontrolled and treated patients with variant angina and normal coronary arteries[21,22]; few trials have involved placebo-treated controls in patients with severe obstructive coronary artery disease and unstable angina pectoris.[24–27] Because there is a considerable variability in the clinical course of patients with unstable angina,[31–33] the use of placebo-controlled double-blind trials is essential in determining efficacy of any new pharmacologic approach. The specialized environment of the coronary care unit by itself may influence the frequency of chest pain in these patients; this finding was evident in that only 15 of 65 patients with a history of unstable angina on admission in the short-term study of Mehta et al.[25] continued to experience episodes of rest angina after treatment with placebo for 24 hours, and thus qualified for eligibility into the study. Robertson et al.[34] also demonstrated that patients with variant or vasotonic angina frequently become symptom-free soon after admission to the hospital. The differences in the magnitude of physical and emotional stress between ambulatory outpatient and inhospital phases may have a bearing on these differences in the frequency of angina. These facts clearly emphasize the need for the use of placebo in determining the efficacy of a drug in relieving symptomatic as well as asymptomatic episodes of myocardial ischemia.

Evidence for effectiveness of verapamil: The two placebo-controlled randomized clinical trials reviewed in this report thus take on particular significance. All patients in both studies had subjective and objective evidence of myocardial ischemia characterized by chest pain and S-T segment changes; most patients also experienced asymptomatic episodes characterized by similar S-T segment changes without chest pain. Before

hospitalization, most patients had a history of exertional as well as rest angina; this angina proved to be secondary to obstructive coronary artery disease in nearly all of the patients evaluated by cardiac catheterization. Verapamil was administered in a double-blind randomized fashion using two different study protocols: the 1st study involved multiple cross-overs from placebo to verapamil and from verapamil to placebo; the 2nd study involved initial randomization followed by cross-over from placebo to verapamil and advancement from a small to a large dose of verapamil. Regardless of the protocol design, both studies indicated that verapamil markedly reduces the frequency of asymptomatic and symptomatic ischemic events in over 90% of all patients with unstable angina.

The beneficial effects of verapamil in patients with unstable angina pectoris evident in these two studies are similar to those reported by Gerstenblith and colleagues with the use of nifedipine.[26] However, important differences between the verapamil and nifedipine trials should be noted. The studies by Parodi et al.[24] and Mehta et al.[25] showed that verapamil therapy provided *short-term symptomatic* benefits in patients with unstable angina with either S-T segment depression or elevation, or both. The Gerstenblith trial did not evaluate the immediate relief of symptoms, but treated patients for 4 months in order to assess the effect of nifedipine on the frequency of failure of medical therapy. Patients randomized to nifedipine were less likely to require surgery for relief of angina than those randomized to placebo; the incidence of sudden death and myocardial infarction was similar in the 2 groups. However, this favorable effect of nifedipine was noted only in those patients with unstable angina who had S-T segment elevations during episodes of rest pain; these findings contrast with those in patients treated with verapamil who were reported improved, regardless of the directional change in the S-T segment during the anginal event. Whether this indicates a real difference in effectiveness between the two drugs in patients with S-T segment depression during episodes of rest angina remains to be determined. Clinical results with *long-term* verapamil administration in patients with unstable angina pectoris, although not placebo-controlled, resemble those of the Gerstenblith study and are reported elsewhere in this symposium.[35]

In conclusion, verapamil therapy is markedly beneficial for the short-term prophylaxis and management of symptomatic and asymptomatic ischemia in patients with severe obstructive coronary artery disease and unstable angina at rest. The drug can produce a rapid stabilization of symptoms greater than can be provided by hospitalization, sedation, intensive observation, and bedrest alone without producing frequent or serious adverse reactions.

Verapamil Versus Propranolol for Angina at Rest

OBERDAN PARODI, MD, IGNAZIO SIMONETTI, MD, ANTONIO L'ABBATE, MD, and ATTILIO MASERI, MD

We previously showed that verapamil is highly effective in the treatment of patients with angina at rest, in whom coronary vasospasm likely represents the primary underlying pathophysiologic mechanism. Beta-adrenergic blocking drugs, on the other hand, do not exert any vasodilating effect on large coronary arteries, and hence do not represent a rational therapeutic approach to the treatment of patients with this syndrome.

The present report reviews the results of three clinical trials comparing the effectiveness of verapamil and propranolol in patients with angina at rest. In 17 patients enrolled in a randomized triple-crossover study, verapamil was superior to propranolol in preventing ergonovine-induced coronary artery spasm ($p < 0.001$). In 18 patients with rest angina evaluated in a double-blind crossover study, both verapamil and propranolol reduced the number of episodes of angina at rest (from 3.0/day to 1.7/day with propranolol, $p < 0.05$, and to 0.2/day with verapamil, $p < 0.001$); the degree of improvement with verapamil was superior to that seen with propranolol ($p < 0.005$). In 10 patients with rest angina evaluated in a single-blind multiple crossover trial which assessed symptomatic and asymptomatic ischemia, the number of ischemic events was reduced significantly only by verapamil (5 ± 1 episodes/48 hours) but not by placebo or propranolol (25 ± 3 and 23 ± 3 episodes/48 hours, respectively).

These studies confirm the effectiveness of verapamil in the management of patients with angina at rest; in contrast, the effectiveness of propranolol in this syndrome appears comparable to that of placebo.

Although propranolol is highly effective in the treatment of patients with angina of effort,[1–4] clinical studies in patients with angina at rest have largely been based on uncontrolled observations and have proved inconclusive.[5–11] The rationale for therapy with propranolol was based on an approach which considered the pathogenesis of chest pain at rest to be similar to that in patients with exertional symptoms. Recent studies, however, have emphasized that angina pectoris can be caused by multiple mechanisms[12] and that coronary vasospasm is responsible for ischemia in a significant proportion of patients with angina at rest.[13,14] Therefore, drugs such as propranolol that primarily reduce myocardial oxygen consumption but fail to exert vasodilating effects on the coronary vasculature may not be effective in patients in whom angina is caused by dynamic alterations in coronary luminal diameter rather than by an increase in myocardial metabolic demands.[15,16] In contrast, calcium channel antagonists can effectively block coronary vasospastic phenomena as well as reduce myocardial work, and controlled clinical trials have shown that these agents produce marked relief of symptoms in patients with angina at rest.[17–20] Among the drugs which have been evaluated, verapamil was the first to be utilized for the treatment of vasospastic coronary artery disease, and it remains our primary drug of choice for the management of patients with angina pectoris.

The present report reviews three objective clinical studies which have compared verapamil to propranolol in the treatment of the patient with angina at rest. The 1st study compares the effects of these drugs in the prevention of ergonovine-induced spasm in patients with variant angina without obstructive coronary artery disease. The second and third studies compare verapamil and propranolol in the short-term management of patients with unstable angina secondary to obstructive coronary artery disease hospitalized in the coronary care unit.

Verapamil Versus Propranolol in Ergonovine-Induced Spasm

Bory et al.[21] investigated the effectiveness of verapamil and propranolol in 17 patients with variant angina without obstructive coronary artery disease.

Patients: All patients had episodes of chest pain at rest associated with characteristic electrocardiographic changes (S-T segment elevation in 12 cases, S-T segment depression in 2 cases, and T-wave inversion in 3 cases); all patients had coronary arteriographic confirmation of coronary artery spasm, which occurred either spontaneously or after provocation with ergonovine.

Trial design: After confirmation of the diagnosis, each patient entered a randomized triple crossover trial in which verapamil (360 mg daily), propranolol (120 mg daily), or placebo was administered for at least 3 days. At the end of each treatment period, ergonovine provocation was performed in each patient 3 hours after the last dose of the drug. Ergonovine was administered as an initial dose of 0.1 mg intravenously, followed by 0.2, 0.3, and 0.4 mg doses every 5 minutes until angina occurred. Treatment was considered completely effective if ergonovine administered in maximal doses failed to produce any symptoms or electrocardiographic changes; partly effective if the dose of ergonovine required to produce a positive response was larger than that needed during initial diagnostic cardiac catheterization; ineffective if the provoking dose of ergonovine was the same as during initial testing; and detrimental if the dose of ergonovine required to provoke ischemia was smaller than during initial provocation.

Results: The results of ergonovine testing are shown in Table I. The test became negative in 3 of 12 patients during treatment with placebo, in 4 of 15 patients during treatment with propranolol, and in 11 of 15 patients during treatment with verapamil; in the 4 patients who still had positive tests on verapamil, the dose of ergonovine required to provoke ischemia was higher than during initial testing. Whereas the responses to propranolol did not differ significantly from those seen during placebo therapy or during initial diagnostic evaluation, verapamil exerted a significant protective effect ($p < 0.001$).

Conclusions: Therefore, verapamil prevented ergonovine-induced spasm in most patients with variant angina, and the drug was superior in doing so to propranolol, which demonstrated little effectiveness in this study. Although the ergonovine test is highly sensitive and specific for variant angina[22,23] and correlates well with the active phase of the disease,[24] the results of this study must be interpreted cautiously. Because of the potential hazard of using ergonovine testing in patients with advanced coronary atherosclerosis, the investigators selected a population of patients with vasospastic angina and essentially normal coronary arteries; however, such patients represent only 7 to 10% of patients with angina pectoris,[12] and thus these results may not be applicable to the majority of patients with angina at rest, in whom coronary vasospasm is superimposed on organic coronary stenosis. Furthermore, it is possible that propranolol might exert favorable effects in patients with angina at rest (i.e., through metabolic alterations or changes in ventricular compliance) regardless of the importance of vasospasm in the specific population being evaluated. Finally, the dose of propranolol (120 mg daily) used in the study of Bory et al. was small and lower than that previously reported to be effective in patients with angina at rest. Therefore, no conclusions regarding the comparable effectiveness of verapamil and propranolol in patients with coronary artery lesions and angina at rest or mixed angina (resting and effort angina) can be drawn from this study.

TABLE I Results of Ergometric Testing Performed Before Therapy and After Treatment With Placebo, Propranolol, and Verapamil*

Verapamil Versus Propranolol in Angina at Rest

Relief of Symptoms

In order to assess the relative effectiveness of propranolol and verapamil in reducing the number of anginal attacks in patients with coronary artery disease and angina at rest, Capucci et al.[25] performed a double-blind, randomized, crossover study comparing placebo, propranolol, and verapamil.

Patients and study design: Eighteen patients entered the study. All demonstrated 2 or more daily episodes of angina at rest associated with electrocardiographic S-T changes; 7 patients showed S-T segment elevation and 11 had S-T segment depression during anginal attacks. Thirteen of the 14 patients in the study who had coronary arteriography had severe obstructive coronary artery disease. The study design consisted of 5 treatment periods: a run-in period (2 days), placebo therapy (2 days), 1st drug (verapamil or propranolol for 4 days), placebo (1 day), and 2nd drug (propranolol or verapamil for 4 days). The dose of verapamil used was 480 mg daily, and the dose of propranolol used was 240 mg daily.

Results: The mean frequency of anginal attacks during the run-in period averaged 3.0 episodes per day and was unchanged by therapy with placebo (3.0 episodes during 1st placebo period and 2.3 episodes during the second placebo period). The number of episodes of angina decreased with propranolol to 1.7/day, significantly fewer than during the run-in and first placebo phases ($p < 0.05$), but not significantly different from the number during the 2nd placebo phase. Verapamil reduced the number of anginal attacks to 0.2/day, significantly fewer than during both placebo periods ($p < 0.001$) and significantly fewer than with propranolol ($p < 0.005$) (Fig. 1).

Conclusions: This study demonstrates that short-term therapy with verapamil is superior to propranolol and placebo therapy in reducing symptoms in patients with coronary artery disease, but these results must also be interpreted with caution. Since angina at rest is characterized by a spontaneous waxing and waning of symptoms, clinical trials of antianginal drugs must include frequent placebo periods in order to detect the possible spontaneous resolution of the disease.[18,26] Hence, the investigators in this study should have incorporated a short placebo period at the end of the trial (after the second drug period) in order to confirm persistence of the disease. In addition, the second placebo period may have been too short to permit adequate washout of the first drug, and thus may not serve as a valid point of comparison. Lastly and most importantly, objective assessment of ischemic episodes was lacking in this trial. Continuous electrocardiographic monitoring performed in patients with angina at rest[12,27] has established that most (50 to 70%) ischemic episodes in such patients are asymptomatic. Since the Capucci trial only assessed symptomatic episodes, the effect of each treatment on total ischemic attacks is unknown; hence, we can draw only limited conclusions concerning drug effectiveness.

Relief of Ischemia

In order to address some of the questions raised by the Capucci trial, Parodi et al.[28] recently completed a randomized single-blind crossover trial comparing the antianginal effects of propranolol and verapamil in patients with unstable angina at rest, hospitalized in a coronary care unit.

Patients: Ten consecutive patients with more than 2 anginal attacks at rest per day were enrolled in the trial; all attacks had confirmation of ischemia by simultaneous electrocardiographic changes. During the ischemic episodes, 3 patients showed S-T segment elevation, 2 S-T segment depression, and 5 S-T segment elevation or depression in different attacks. All but one patient had severe obstructive coronary artery disease by coronary arteriography.

Study design: The protocol began with a 2 day placebo run-in period followed by a 14 day single-blind protocol consisting of seven 48 hour treatment periods. Half of the patients received verapamil-placebo-propranolol-placebo-verapamil-placebo-propranolol; the other half received propranolol-placebo-verapamil-placebo-propranolol-placebo-verapamil. Hence, verapamil and propranolol were each administered for two 48 hour periods during the 2 week trial, and each of the active drug therapies was separated by a 48 hour placebo treatment period. Propranolol was given as 300 mg daily and verapamil as 400 mg daily. Prophylactic use of short- or long-acting nitrates was not allowed during the study; sublingual nitroglycerin was allowed only as treatment for anginal attacks. Oscilloscopic and Holter monitoring was performed throughout the trial in order to assess asymptomatic periods of ischemia.

A total of 1,582 episodes of symptomatic and asymptomatic ischemia were recorded during the trial, of which 685 (43%) were asymptomatic. The total number of ischemic episodes for each treatment period is shown in Figure 2. The mean number of events during the four placebo periods was 25 ± 3 attacks per 48 hours;

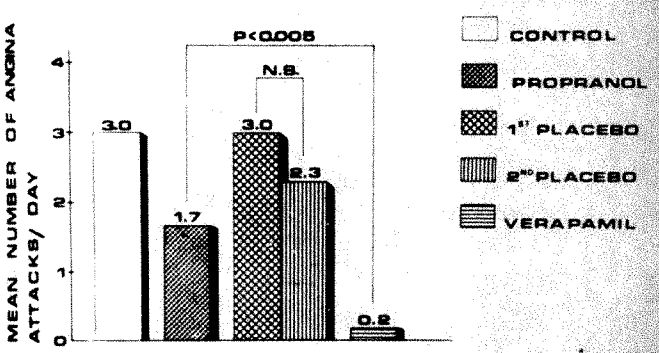

FIGURE 1. Overall results of a double-blind single crossover study of propranolol versus verapamil in 18 patients with unstable angina. (Reproduced, with permission, from Capucci et al.[25])

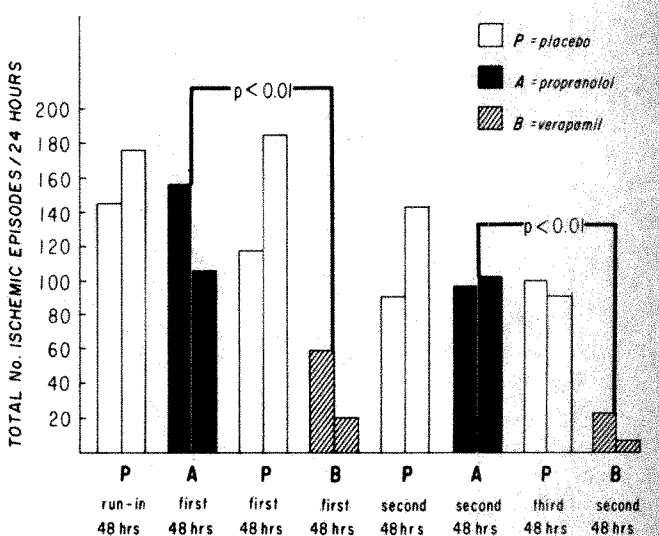

FIGURE 2. Overall results of a single-blind double crossover study in which propranolol (A) and verapamil (B) were compared in 10 patients with frequent ischemic attacks at rest. Every 48 hour period of treatment with each active drug is matched and compared with a 48 hour placebo period (P).

this was not significantly reduced during the 2 propranolol treatment periods (23 ± 3 episodes per 48 hours) but was reduced significantly during treatment with verapamil (5 ± 1 events per 48 hours) ($p < 0.01$ versus placebo and propranolol). Similarly, the number of nitroglycerin tablets consumed during placebo treatment (17 ± 2 tablets) was not significantly reduced by propranolol (14 ± 2 tablets) but was decreased by verapamil (2 ± 1 tablets) ($p < 0.01$). However, such averages mask a spontaneous decrease in the number of ischemic episodes noted during the performance of the trial; 312 episodes were noted during the first 48 hours of treatment with placebo, but the number decreased to 296, 229, and 184 events during the 2nd, 3rd, and 4th placebo periods ($p < 0.05$ between the 4th and 1st phases). A similar decrease in the number of ischemic events, however, was noted for the treatment periods (250 and 213 events for 1st and 2nd propranolol periods, respectively [$p > 0.10$]; 73 and 25 events during the 1st and 2nd verapamil periods, respectively [$p < 0.05$]).

The frequency pattern of ischemic attacks in two of the patients in the trial (Fig. 3) illustrates the importance of a multiple crossover protocol in assessing the effectiveness of drug therapy. If, in the patient shown in the left panel of Figure 3, the study had been stopped at the end of the first crossover period, propranolol and verapamil would have appeared to have a similar efficacy; the second half of the trial demonstrates, however, that only verapamil exerted a consistent and reproducible effect on the incidence of ischemic episodes. In the patient shown in the right panel of Figure 3, we observed a progressive reduction in the number of ischemic episodes throughout the trial; nevertheless, verapamil completely abolished the attacks during both 48 hour phases.

This is a preliminary report on the clinical results obtained during the trial. A complete analysis of the other results of the study (arrhythmias, magnitude and length of ischemic episodes, incidence and severity of asymptomatic versus symptomatic episodes as detected by Holter monitoring) is still in progress.

Conclusions and limitations: Although this trial does not support the use of propranolol in patients with angina at rest, such a conclusion should be interpreted cautiously. One of the 10 patients in this study had a reproducible decrease in ischemic episodes with propranolol comparable to that seen with verapamil; this suggests that propranolol may be effective in some patients with angina at rest. Furthermore, it is possible that doses higher than 300 mg of propranolol daily might have produced more marked beneficial responses than those seen in this study. Although the doses of propranolol used were sufficient to achieve beta-blockade and were comparable to those currently used in the management of patients with unstable angina, higher doses have been reported effective in reducing the incidence of ischemic episodes at rest.[29] Unfortunately, individual responses to propranolol vary widely, and thus the rather arbitrary choice of a dose of propranolol for purposes of comparison may bias any study against finding a beneficial effect of the drug.

Discussion

Effect of propranolol and verapamil on coronary spasm: Since coronary vasospasm has been shown to be a frequent cause of transient myocardial ischemic attacks at rest, drugs which have coronary spasmolytic effects should play a pivotal point in any rational therapeutic approach to patients with this syndrome. Although propranolol has long been used to treat patients with rest angina, beta-blockade results in significant constriction of large coronary vessels, an effect which is potentially detrimental in patients with unstable angina at rest.[30–32] In contrast, experimental and clinical studies[33–36] have demonstrated the potent vasodilating effect of verapamil on large coronary ar-

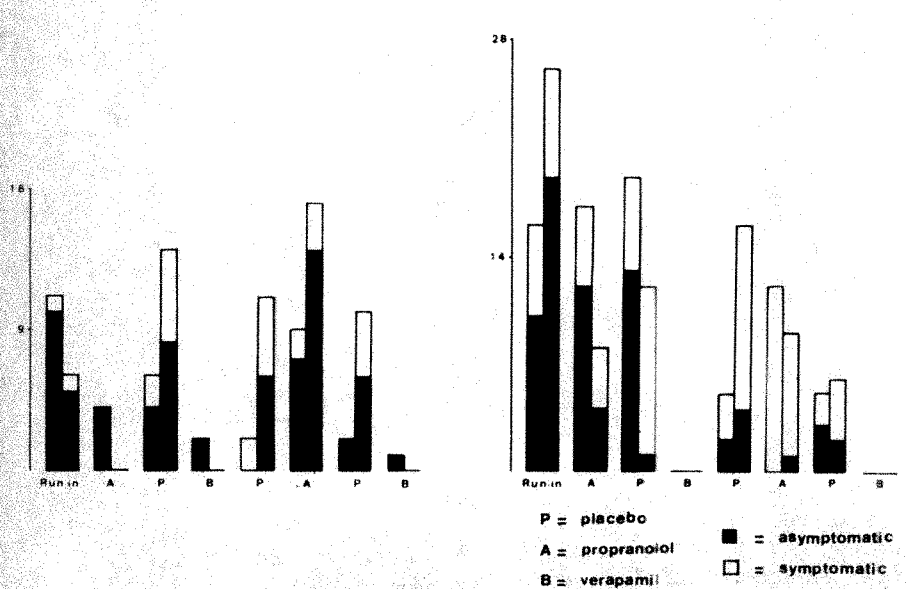

FIGURE 3. Histogram showing the incidence of ischemic episodes in Patients 1 (**left panel**) and 10 (**right panel**) with placebo (P), propranolol (A), and verapamil (B). The importance of using crossover periods in short-term trials in angina is illustrated in these two examples. See text for details.

teries; this vasodilation can be observed in man in both normal and atherosclerotic coronary segments and is comparable to that induced by nitroglycerin.[36] In addition, coronary vasospasm resolves after the intracoronary injection of verapamil.[37]

The results of Bory et al.[21] demonstrate that verapamil but not propranolol antagonizes the ability of ergonovine to provoke coronary vasospasm in patients with variant angina; the effectiveness of verapamil in such patients is in agreement with the observations of Waters et al.[38] No study has demonstrated a protective effect of propranolol in vasospastic disorders.

Verapamil versus propranolol in angina at rest: Both of the clinical trials reviewed herein indicate that verapamil is highly effective and superior to propranolol in the management of patients with unstable angina at rest.[25,28] These findings support previous controlled clinical trials comparing verapamil with placebo which demonstrated the value of calcium antagonists in the management of patients with coronary artery disease and symptoms at rest.[17,18]

In contrast to verapamil, propranolol was found to have little or no effect on the incidence of ischemic events at rest; this finding contradicts the favorable clinical experiences with propranolol in unstable angina reported by Papazoglov,[5] Mizgala,[6] Fischl,[7] Guazzi,[29] and their co-workers. Unfortunately, such experiences were largely uncontrolled and did not consider the natural course of the disease, since many patients with unstable angina have spontaneous remission of symptoms.[27,28] In the patients treated by Parodi et al., propranolol neither aggravated ischemia nor provided any protective effect; this is consistent with previous clinical reports.[8–11]

Although not seen in the 2 clinical trials cited in this report, beta-blockade can produce detrimental effects in patients with vasospastic angina. Yasue et al.[39] observed worsening of angina with propranolol in 13 patients with chest pain associated with S-T segment elevation. Robertson et al.[40] found that propranolol significantly prolonged the duration of ischemia as assessed by electrocardiographic monitoring in some patients with vasospastic angina; most of their patients, however, failed to notice any worsening or improvement of angina while taking propranolol despite the use of up to 640 mg daily of the drug. On the other hand, the finding of occasional responders to propranolol therapy (as documented in a single case in the study by Parodi et al.) suggests that this treatment may work in some individuals. This underscores the concept that mechanisms responsible for primary angina and vasospasm are multiple and remain largely unknown.

Although many investigators have reported beneficial results with the combination of verapamil and propranolol in angina of effort,[41,42] we do not recommend this combination in the treatment of angina at rest. Over the last decade, we have observed severe side effects caused by combination therapy consisting of bradycardia, transient asystole, severe hypotension, atrioventricular block, and congestive heart failure. Since the advantages of combination therapy in the management of rest angina lacks sound theoretical support, the frequency of adverse reactions has led us to avoid combination verapamil-propranolol treatment in patients with this syndrome.

Controlled *long-term* randomized trials comparing verapamil and propranolol in patients with angina at rest are yet to be performed. Thus, the controversy about the choice of the best medical long-term treatment in angina at rest has not been resolved.

Conclusions: Treatment with adequate dose of oral verapamil (360 to 480 mg daily) combined with long-acting nitrates appears to be the most effective and most rational therapy for patients with unstable vasospastic angina at rest. Although propranolol has been long considered the first-choice drug in most patients with angina pectoris, the drug does not appear useful in the management of most patients with this syndrome. The eventual place of propranolol in the management of unstable angina needs to be clarified and awaits a better understanding of the pathophysiology of ischemic heart disease.

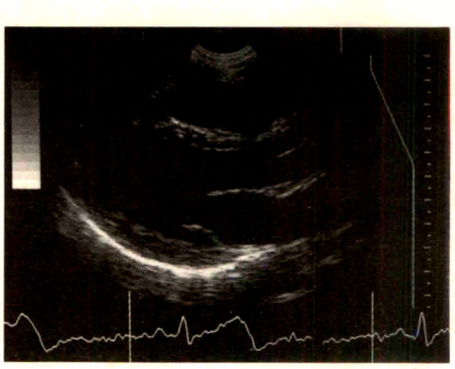
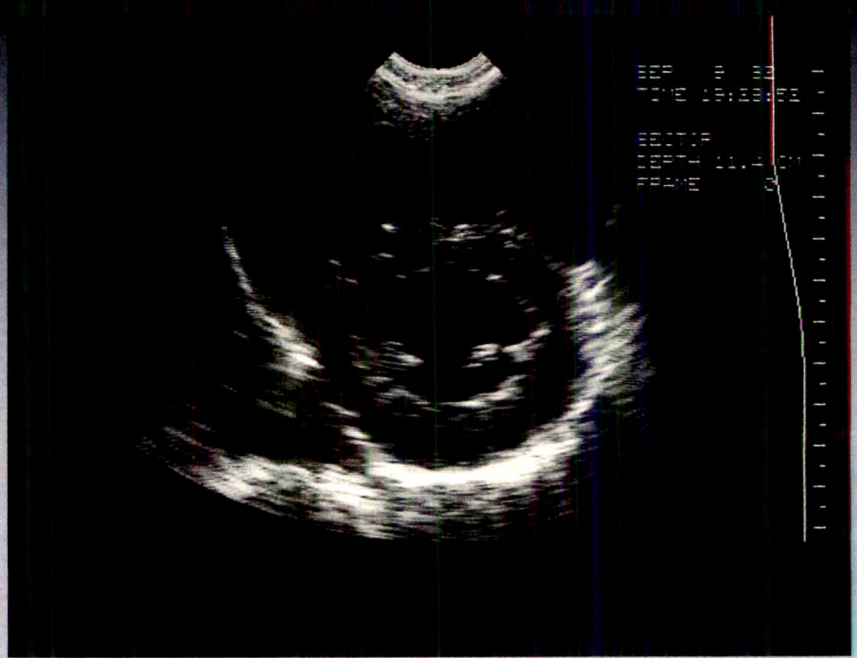
TODAY, ATL BRINGS A NEW GENERATION OF IMAGE QUALITY TO CARDIOLOGY.



SIX REASONS WHY ATL
THE INDUSTRY STANDAR



1. *Spatial Accuracy*
2. *Precise Definition of Wall Boundaries*
3. *Noise Free Cardiac Chambers*

Ever since 1979 when ATL introduced the first 2-D digital sector image, our image quality has been everyone's standard for comparison.

Today, with the introduction of CardioSeries,™ ATL presents the cardiologist with a new generation of echocardiography systems featuring the most accurate 2-D images available.

Here is image quality you can see: greater penetration, higher resolution, more precise definition of cardiac boundaries, detailed grey scale mapping and noise free chambers.

The 2-D echoes above illustrate these criteria clearly. We invite you to see a demonstration of ATL's new CardioSeries.

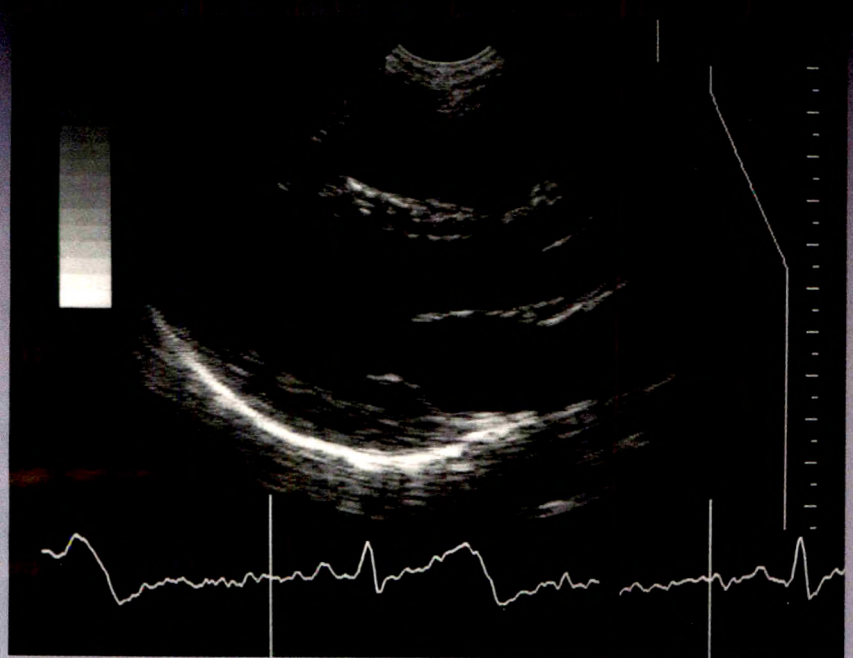
What you will see is a true advancement in 2-D image quality. An advancement made possible by technological improvements in the echo receiver, digital scan converter and scanheads. These improvements together provide a better collection of pure diagnostic data and therefore more precise echoes.

CardioSeries Takes High Resolution Ultrasound To Greater Depths. ATL's new CardioSeries provides increased penetration at all frequencies. Now, a greater percentage of adults, in addition to your pediatric patients, can be examined with excellent results using a 5 MHz scanhead.

Extended Grey Scale and Post Processing. With better than 7-bit image display precision, CardioSeries provides a very precise definition of cardiac wall boundaries, valves and most importantly, visualization of possible life threatening apical clots and thrombi.

Furthermore, eight post-processing functions enable optimal assignment of specific

IEW CARDIOSERIES™ IS
OR 2-D ECHOCARDIOGRAPHY.



4. *Near Field Resolution*
5. *Far Field Resolution*
6. *Detailed Grey Scale Mapping*

grey scale values anytime during the examination.

A New M-mode Concentrates On Your Concerns. The new M-mode of CardioSeries gives you more flexibility and information than ever before. The selectable pre-processing curves help focus on specific areas of interest. The M-mode's wide range grey scale presents greater tissue texture information, and selectable edge enhancement provides precise cardiac boundary definition without compromising the grey scale presentation.

A Direct Link To Off-Line Analysis. With CardioSeries you are one step closer to the future of off-line computer analysis. Each system includes a Data Port through which unprocessed digital image information can be transmitted to an external computer.

Add CardioSeries Capabilities To Your Existing ATL System. Enhance your MK 300 or MK 500 system performance and protect your original investment against obsolescence by upgrading with CardioSeries capabilities.

Compare ATL's performance with any other. Compare penetration, resolution and overall image quality. Decide for yourself which 2-D echo is best. Call ATL. We will demonstrate our CardioSeries echocardiography systems against any other.

ATL™ ultrasound

THE MEASURABLE ADVANTAGE IN ECHOCARDIOLOGY

NEW FROM ATL. CARDIOSERIES™— THE MEASURABLE ADVANTAGE IN ECHOCARDIOLOGY

CARDIOSERIES IS ANOTHER EXAMPLE OF ATL'S CONTINUING ADVANCEMENTS IN ECHOCARDIOLOGY.

CardioSeries is an improvement you can see, an improvement you can measure. This continuing effort for technical advancement is the reason more ATL echocardiography systems have been installed in the past three years than those of any other 2-D company.

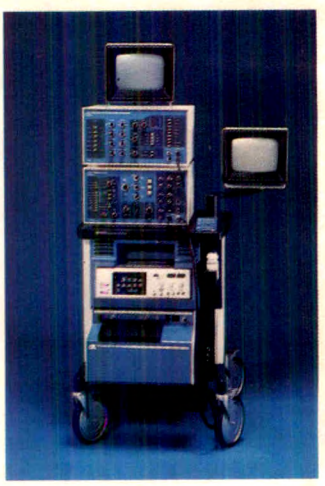
ATL, A CONSISTENT LEADER IN ECHOCARDIOLOGY.

- □ Founded in 1974
- □ First digital scan converter for Real-time ultrasound
- □ First 90° 2-D sector
- □ First pediatric 5 MHz 2-D probe
- □ First dual frequency Doppler system
- □ First duplex Doppler and Real-time system, 1978
- □ First clinically proven pulsed Doppler technology

CARDIOSERIES, A NEW GENERATION OF IMAGE EXCELLENCE.

- □ 90° full-view 2-D sector
- □ 16 precise depth settings
- □ Up to 45 frames per second
- □ Seven cardiology scanheads
- □ Selectable grey-scale M-mode
- □ Increased penetration and improved overall image quality
- □ Better than seven bit image display precision
- □ 8 post processing transfer curves.

The New CardioSeries MK 300LX, a low cost, dedicated 2-D ultrasound system.



The New CardioSeries MK 500 CX, a high performance 2-D, M-mode and pulsed Doppler ultrasound system.

The New CardioSeries M 300C, a high performance 2-D, and M-mode ultrasound system.

ATL ultrasound

THE MEASURABLE ADVANTAGE IN ECHOCARDIOLOGY

Yes, I would like to know more about CardioSeries ultrasound, the measurable advantage in echocardiology.

Please return this response form to ATL, or phone (206) 881-2233.

WITHDRAWAL OF 2 PREVIOUSLY PUBLISHED REPORTS

During 1981 I became aware of irregularities in data collected in my laboratory, as described in Section II of the Report of an Ad Hoc Advisory Committee to the Dean of the Harvard Medical School (*Harvard University Gazette*, January 29, 1982, Volume 77, page 1; and *Nature*, December 24, 1981, Volume 294, page 684).

This problem and further investigation have brought into question the validity of the data in the 2 reports listed below:

1. **Darsee JR, Kloner RA.** Dependency of location of salvageable myocardium on type of intervention. Am J Cardiol 1981;48:702–710.
2. **Darsee JR, Kloner RA.** The no reflow phenomenon: a time-limiting factor for reperfusion after coronary occlusion? Am J Cardiol 1980;46:800–806.

Because of the circumstances referred to above, it is my opinion that these reports should be retracted.

However, additional experiments have been carried out in my laboratory to examine the validity of the conclusions in these reports. These have validated the conclusions in the first report that drugs may result in both a lateral and subepicardial zone of salvage. These findings have been published. The observation that reperfusion results mainly in subepicardial salvage and the major concept in the second report that zones of microvascular damage occur within zones of myocardial cells which are already irreversibly damaged has also been confirmed, and the results have been submitted for publication.

Robert A. Kloner, MD, PhD, Department of Medicine, Harvard Medical School, Brigham and Women's Hospital, Boston, Massachusetts 02115

PROPER IDENTIFICATION OF TRADEMARKED PRODUCTS

I call your attention to an article in your March issue (Fuchs RM, Heuser RR, Yin FCP, Brinker JA. Limitations of pulmonary wedge V waves in diagnosing mitral regurgitation. Am J Cardiol 1982;49:849–854), in which the term "Swan-Ganz catheterization" is used to refer to a catheterization presumably performed using a flow-directed thermodilution catheter. Swan-Ganz is a registered trademark of American Hospital Supply Corporation, U.S. Trademark Registration No. 929,651. The term "Swan-Ganz" is registered for use with catheters. To use it, as the article does, to describe a surgical procedure is a misuse which, if repeated continually, would weaken and diminish our exclusive rights to use the Swan-Ganz trademark to identify our products.

We recognize that the article in question was submitted to you in approximately its present form and that the authors of the article and not your editors chose the term. It is nevertheless our hope that, by acquainting you with our concerns, we can enlist your cooperation for the future in using our Swan-Ganz trademark properly.

Enclosed is a brochure on proper trademark usage distributed by the United States Trademark Association. It is not our intent to presume to instruct the *Journal* and its editors on proper trademark usage, but instead to lend some authenticity to the need for proper use of our trademark by members of the public such as yourselves. Rule 6 in the brochure refers to the need and desirability of using a trademark to refer to the finished product and not to some other material or procedure. Thus, "Swan-Ganz catheter" or "Swan-Ganz thermodilution catheter" is a correct usage; "Swan-Ganz catheterization" or "Swan-Ganz balloon" is not. Your cooperation in using our Swan-Ganz mark in the recommended manner will be appreciated.

Robert E. Hartenberger, Trademark Counsel, American Hospital Supply Corporation, One American Plaza, Evanston, Illinois 60201

THE MORPHOLOGIC METHOD APPLIED TO THE PROBLEM OF "SINGLE" RIGHT VENTRICLE

Although Shinebourne et al.[1] claim to present 18 cases of single right ventricle ("univentricular heart of right ventricular type"), in fact they presented none. In addition to a large morphologically right ventricle, all of their cases also had a small morphologically left ventricle (LV). In single right ventricle, the left ventricle is absent (by definition), not just small.[2,3] Although the authors[1] presented no case of single right ventricle, which is a rare malformation,[2,3] they did make a good presentation of double inlet right ventricle, common inlet right ventricle, and mitral atresia in biventricular hearts with a large right ventricle and a small left ventricle.

The basic problem with the paper by Shinebourne et al.[1] is that these authors essentially accepted *the classic definition of single ventricle*[2,3]—that single ventricle is present when both atrioventricular (A-V) valves or a common A-V valve opens entirely or predominantly into 1 ventricular chamber. Unfortunately, this old definition leaves much to be desired. Briefly:

1. It is *wrong in principle* because it embodies an error in logic. This old definition attempts to define 1 variable (the anatomic status of the ventricles) primarily in terms of another variable (the anatomic status of the A-V valves). Instead, each variable should be defined primarily in terms of its own characteristics. For example, the anatomic status of the ventricles should be defined in terms of the morphologic characteristics of the ventricular portion of the heart, not in terms of any other variable, such as the A-V valves or the semilunar valves.

2. This old definition *violates the morphologic method* of diagnosing and naming the cardiac chambers in congenital heart disease. This method, which was introduced by Lev[4] in 1954 and has subsequently proved essential to the understanding of complex congenital heart disease,[2,3,5] may be stated as follows: (A) Cardiac chambers are diagnosed and named by means of their gross myocardial morphologic characteristics. (B) Cardiac chambers are not diagnosed and named by means of their vessels or *valves* of entry or exit, nor in terms of relative positions (such as right- or left-sided), nor in terms of the type or types of blood conveyed (such as arterial or venous), because all of these considerations are variables in congenital heart disease.

* Letters concerning a particular article in the *Journal* must be received within 2 months of the article's publication.

It is noteworthy that diagnosing and naming the anatomic status of the ventricles by means of the entering A-V valve or valves is specifically prohibited by the morphologic method. Unfortunately, this is precisely what the old definition of single ventricle attempts to do.

3. Because the classic definition of single ventricle is wrong in principle and is an unwitting violation of the morphologic method, it is not surprising that it has *numerous exceptions*. (A) Double inlet right ventricle and common inlet right ventricle may or may not have single right ventricle. Usually such hearts do *not* have a single right ventricle, accurately speaking; in terms of morphologic anatomic analysis, a small left ventricle usually also coexists. This is by far the most common exception to the classic definition of single ventricle. Ironically, this is the exception that was well explored by Shinebourne et al.[1] and was previously considered by Soto et al.[6] (B) With a single left ventricle, the straddling tricuspid valve can open predominantly into the infundibular outlet chamber, instead of predominantly into the single left ventricle as required by the classic definition. This anomaly is known as the *Lambert heart*.[7] (C) With a single left ventricle the tricuspid valve can open *exclusively* into the infundibular outlet chamber,[8] instead of predominantly into the single left ventricle as is required by the old definition.

Since the old definition of single ventricle is clearly unsatisfactory (being wrong in principle and a violation of the morphologic method and having at least 3 different types of exceptions), it should not be used as a model (paradigm) for the redefinition of single ventricle, nor for the redefinition of similar conditions such as straddling A-V valves and atretic A-V valves, nor for the redefinition of what is a *ventricle*, as opposed to what is merely a *rudimentary chamber*, as Shinebourne and his colleagues[1,9,10] have attempted to do.

For example, Shinebourne and his associates[1,9,10] have stated that when a straddling mitral valve opens 51 percent into the left ventricle and 49 percent into the right ventricle, then the left ventricle is called "the left ventricle" and the right ventricle is called "the right ventricle." However, when the straddling mitral valve opens only 49 percent into the left ventricle and 51 percent into the right ventricle, then the left ventricle must not be called "a left ventricle," but "a rudimentary chamber of left ventricle type," and the right ventricle must not be called "a right ventricle," but "the main chamber of a univentricular heart of right ventricle type."

There is much that is wrong with this approach.[1,9,10] First, the real reason for this assertion is failure to appreciate the deficiencies of the classic definition of single ventricle, on which this distinction between a ventricle and a rudimentary chamber is based. By essentially accepting the classic definition of single ventricle and attempting to build on it, Shinebourne and his colleagues[1,9,10] have unfortunately built on sand.

In view of its aforementioned deficiencies, the old definition of single ventricle must be supplemented by morphologic anatomic analysis[2,3] in order to ensure anatomic accuracy. Whenever conclusions based on morphologic analysis come into conflict with interpretations based on an old definition (such as that of single ventricle), the results of morphologic analysis should be preferred—particularly when the old definition is flawed, as in the case of the old definition of single ventricle.

To say that a left ventricle is not a left ventricle unless it receives 50 percent or more of the mitral valve is analogous to saying that the morphologically left atrium is not the left atrium unless it receives at least 2 of the 4 pulmonary veins. However, in totally anomalous pulmonary venous connection, the left atrium is still the left atrium, even though it receives no pulmonary veins. In total anomalous pulmonary venous connection, although the left atrium is not normal, it is a left atrium nonetheless. To call the left atrium "an accessory chamber" would serve no useful purpose and would merely be another violation of the morphologic method and of the aforementioned principle of logic.

Taxonomically, this approach[1,9,10] is not practical. For example, it is not helpful for the names of the ventricular chambers to change depending on the degree of straddling of the A-V valves.

Anatomically, this approach[1,9,10] is not realistic. A straddling mitral valve is not 51 percent above the left ventricle and 49 percent above the right ventricle, or vice versa. In both hypothetical situations, the straddling mitral valve is mainly above the ventricular septum. The foregoing is conceptual anatomy, not realistic anatomy.

Diagnostically, this approach[1,9,10] is not practical. Angiocardiographically, echocardiographically, and even surgically, one cannot distinguish 51 percent straddling of the mitral valve or tricuspid valve from 49 percent straddling.

Surgically, this approach[1,9,10] is not helpful. For example, just because the straddling tricuspid valve opens more into the left ventricle than into the right ventricle, it does not necessarily follow that a single left ventricle is therefore present. In this situation, a good-sized right ventricle can coexist and this anatomic fact can be of considerable surgical importance. Anatomic inaccuracy is not helpful surgically.
